Method.—Take about 10 ml. of urine in a test-tube. Add about 0.25 ml. of silica gel powder by means of the scoop. Shake up the powder in the urine at intervals of 1 or 2 minutes by holding the top of the tube and swirling sharply once or twice. After ten minutes allow the tube to stand for a minute or two while the powder settles and then gently pour off the urine. Add a few millilitres of water, allow the powder to settle again, and gently pour off the water. A brown coloration of the silica gel indicates the presence of bile pigments. Mepacrine is also absorbed in these conditions, but its presence can be determined from the history of the patient and by the yellow colour developed on the adsorbent.

Sensitivity.—Some deeply coloured urines, containing no bile pigments, give a slight yellowish-brown colour. This is readily distinguished from the deeper and browner colour produced by even small quantities of bile pigment. By making dilutions of urine containing excreted bile pigments it was shown that the method of "adsorption colorimetry" will readily detect appreciably smaller quantities of pigment than those detected by the current "bedside" tests. It is, for example, about 15 times more sensitive than the iodine test and about 8 times more sensitive than Gmelin's (nitric acid) test. It compares favourably with the more elaborate laboratory tests, being, for example, only slightly less sensitive than the Fouchet test. With pure bilirubin dissolved in urine the approximate limits of sensitivity were as follows:

Test	Minimal Detectable Concentration, mg/100 ml.
Iodine	3
Gmelin's	1.5
Silica gel	0.2
Fouchet	0.1

Comment

An indication of the usefulness of the test in practice is given by the results of the analysis of 100 samples of urine. Of these, 58 samples were negative by all of the four tests mentioned; 42 were positive by both the adsorption and the Fouchet test; 8 were also positive by Gmelin's test; and only one was positive by the iodine test. All but one of the 42 positive samples were from patients with known hepatic damage. In these instances, therefore, the adsorption test was just as useful as the more elaborate Fouchet test and decidedly more useful than Gmelin's or the iodine test.

Silica gel powder, already sifted, may be obtained from Silica Gel, Ltd., Aldwych House, W.C.2.

Major Rolfe M. Harvey (*Amer. J. Roentgen.*, 1944, **52**, 487) states that 18 of 500 consecutive cases of atypical pneumonia had fractured ribs, and in 9 of them the fractures were multiple. The occurrence of these fractures was not related to the severity of the pneumonia, and he believes they are caused by the severe, dry, irritating cough of this condition. He therefore suggests that, when excessive pain in the chest arises in the course of an atypical pneumonia and is difficult to account for by pleurisy, the possibility of a fractured rib should be borne in mind.

Reviews

SEX ENDOCRINOLOGY

Office Endocrinology. By Robert B. Greenblatt, M.D., C.M. Second edition. With foreword by G. Lombard Kelly, M.D. (Pp. 243; illustrated. 22s.) Springfield and Baltimore: Charles C. Thomas; London: Baillière, Tindall and Cox. 1944.

This small, eminently practical, and informative book can be thoroughly recommended to those who are overwhelmed by the intricacies of present-day endocrinology, and have need of a simple and direct guide to the use of hormones in practice. The subject-matter is limited almost entirely to male and female sex endocrinology, and consists of a collection of post-graduate lectures in an abbreviated form. Theoretical and experimental data are mostly omitted, though there are chapters on the development of the gonad and the physiology of the ovary and menstruation—and excellent chapters they are, stating the latest views concisely and simply and giving just enough information to provide the background for hormone therapy. Not only is the management of such conditions as amenorrhoea, menorrhagia, and cryptorchism described, but also the more difficult and obscure symptom-complexes such as obesity, libido, hirsuties, menstrual malaise, headaches, and nervous-tension states. Full details of hormone preparations and dosage are given throughout, and there is a valuable summary of the main actions of the various principles, together with a list of their proprietary preparations (British ones unfortunately omitted). Simple diagnostic techniques, such as endometrial biopsy, vaginal smear examination, testicular biopsy, and the method of implanting hormone pellets, are also described.

The book bears witness to some differences in outlook which obtain in America as compared with this country. Thus there is only scanty reference to stilboestrol and other synthetic oestrogens which have never found much favour in the U.S.A. On the other hand, male hormone therapy for disorders in the female, which is not extensively employed in this country, is recommended, often as the treatment of choice, for nearly every condition mentioned. Such treatment is comparatively new and its proper place has not yet been determined, but it evidently has a strong advocate in Prof. Greenblatt.

Many will object to the use of the term "medical curettage" to denote the induction of uterine haemorrhage or endometrial shedding by hormonal means, but the book contains little that warrants criticism. It is both instructive and fascinating, and those who turn to it as a practical guide can hardly fail to be stimulated to pursue the subject further in the more academic writings to which reference is made at the end of each chapter.

ARTIFICIAL PNEUMOTHORAX

Artificial Pneumothorax in Pulmonary Tuberculosis: Including its Relationship to the Broader Aspects of Collapse Therapy. By T. H. Rafferty, M.D. Introduction by Henry Stuart Willis, M.D. (Pp. 192; illustrated. $4.00 or 21s.) New York: Grune and Stratton; London: William Heinemann.

Artificial pneumothorax has been increasingly used during the past 25 years at least, yet (as Dr. Henry Stuart Willis puts it in the introduction) "a detailed study from England a few years ago left one in a totally equivocal state of mind as to its merits." He presumably refers to F. J. Bentley's report to the M.R.C. in 1936 on "Artificial Pneumothorax: Experience of the London County Council." But Dr. Rafferty shows how impossible it is to assess statistically "the real long-term value" of artificial pneumothorax, particularly as not enough material of patients treated on modern lines and followed up for an adequate period is at present available. Nevertheless he leaves little doubt about its important place in the treatment of pulmonary tuberculosis provided indications and management are based on certain definite principles—principles that must show full appreciation of the differences between effective and ineffective pneumothorax, and include wider use of bronchoscopy and pneumonolysis. Complications occur or bad *remote* results will often follow when these principles are ignored.

While it is now generally recognized that collapse measures other than artificial pneumothorax are preferable in certain circumstances, it may appear revolutionary to reject the idea long held that an artificial pneumothorax should always be attempted before a thoracoplasty is done. But the technique and results of this operation have so greatly improved in recent years that a *primary* thoracoplasty is, according to Dr. Rafferty, indicated (1) in those in whom the extent of the disease calls for permanent collapse, (2) in those in whom there is great risk of pleural infection, and (3) in those in whom interference with bronchial drainage, due to bronchial tuberculosis, renders pneumothorax dangerous. From this we may anticipate the author's clear demonstration of the danger signs in artificial pneumothorax if complications are to be avoided. Of special interest in this connexion should be the sections on tracheobronchial tuberculosis and on the tension cavity—subjects which have only very recently received the attention they deserve. It should no longer be necessary to stress the very important role of pneumonolysis in obtaining an effective pneumothorax, but Dr. Rafferty maintains that "logic and increasing experience therefore seem to dictate the course of severing nearly all adhesions that can be severed with safety, unless there are definite contraindications or unless the adhesions clearly are removed from the diseased areas." Moreover, he leaves the impression that complications after pneumonolysis should be rare if the operation is done wisely, early, and well. Since there is a general tendency to be reluctant to abandon a pneumothorax (and in this one is perhaps influenced by the possible immediate psychological reaction of the patient), Dr. Rafferty rightly insists that artificial pneumothorax should be regarded as an exploratory procedure, to be abandoned at once, before any harm ensues, if it proves inadequate—to be regarded thus, we would add, by the patient as well as by the physician.

In the concluding chapter certain minimum standards are suggested as "possibly adequate" in the application of collapse therapy. No one who has studied this monograph will consider these too exacting, or fail to be convinced that the treatment of pulmonary tuberculosis should be undertaken only in institutions where full surgical facilities are immediately available.

This is evidently not intended to be a comprehensive text-book on collapse therapy of pulmonary tuberculosis, so that a few omissions or scant consideration of some aspects of the subject may be forgiven. But, in addition, the author leans very heavily indeed on the results of other workers, the illustrations are few and the skiagrams not well reproduced, and the style is often ponderous or tends to suggest dogmatism, which may alienate some readers. Nevertheless most will agree with Dr. Willis that "the refreshing point of view which Dr. Rafferty presents in his book bespeaks the best thought on this subject." Certainly no one connected with the treatment of pulmonary tuberculosis should fail to read the book. It should perhaps be mentioned that phrenic paralysis followed by pneumoperitoneum is not discussed, but this combined collapse measure has only very recently been introduced, and its use in relation to collapse therapy as a whole must still be regarded as in an experimental stage.

CHILD GUIDANCE

An Introduction to Child Guidance. By W. Mary Burbury, M.B., B.S., D.P.M., Edna M. Balint, B.Sc., and Bridget J. Yapp, M.A. (Pp. 200. 7s. 6d.) London: Macmillan and Co. 1945.

This is an excellent little guide to the whole subject of child guidance written by a team of experienced and enthusiastic workers who know how to collaborate and pool their knowledge. It is written in simple language and is easy to read, even by those not versed in modern psychological technicalities, and can be strongly recommended not only to doctors but to all who are interested in the social services. The book makes it clear that in guiding the child it is essential that the whole situation in which the child finds himself—home, street, and school—must be studied, and that both the child's relations to others and their reactions to him must be fully appreciated, hence the value of the team of psychiatrist, educational psychologist, and psychiatric social worker. The psychological treatment of the child is quite different from that of the adult, since he cannot be expected to co-operate verbally and intellectually as does the grown-up. Emotional rapport is necessary, however, and none will be successful with him who does not love children. Play, drawing, story-telling, and indirect implications from observations at home and at school, of parents and-teachers, are used. There is little formal analysis even with adolescents, but an indirect application of analytical knowledge is essential.

It is of course impossible to convey on paper exactly how child guidance is done, because each case is an individual problem which is worked out as much by the emotional rapport of all those concerned as by any formal process, but those who wish to know as much as possible about the subject without learning and practising the art themselves should read this book.

Notes on Books

A yearbook which we had hoped not to see again in its existing form is the *Fire Protection and A.R.P. Year Book* (London: Lomax, Erskine and Co. Ltd.; 7s. 6d. post free), but with the prolongation of the war the letters "A.R.P." still have a lively meaning. This little annual contains an extraordinary amount of well-compacted information on various aspects of civil defence. The section on equipment for first-aid stations, rescue parties, wardens' posts, and ambulance satchels is particularly useful, and so are the articles interpreting recent Acts of Parliament and statutory rules and orders. There is also a directory of various services. We hope that next year this work will appear in "civvies"; there is scope for a manual of the kind in peacetime. Ordinary fires, apart from those due to enemy action, are said to be on the increase, and the toll of accidents on the roads and in industry is hardly likely to grow less, so that to keep as many people as possible informed on fire protection and first aid will be a useful service.

A pamphlet on *The Estimation of Vitamin A*, by Mr. N. T. Gridgeman of the Research Laboratories of Lever Brothers and Unilever Ltd., Port Sunlight, Cheshire, has been privately printed, and copies are being distributed free of charge to many individuals, institutions, and libraries. Application should be made to the author, care of the company at that address.

Preparations and Appliances

TWO PIECES OF SUCTION APPARATUS

Lieut. P. F. Jones, R.A.M.C., writes:

I have recently heard that two simple pieces of apparatus employed by me as a house-surgeon have been found of continuing use in the hospital. No originality is claimed for the fundamentals of either apparatus, but as they require no special materials in their assembly I venture to present them here.

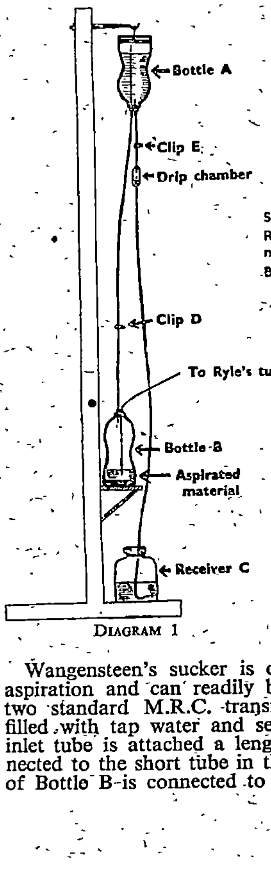

Diagram 1

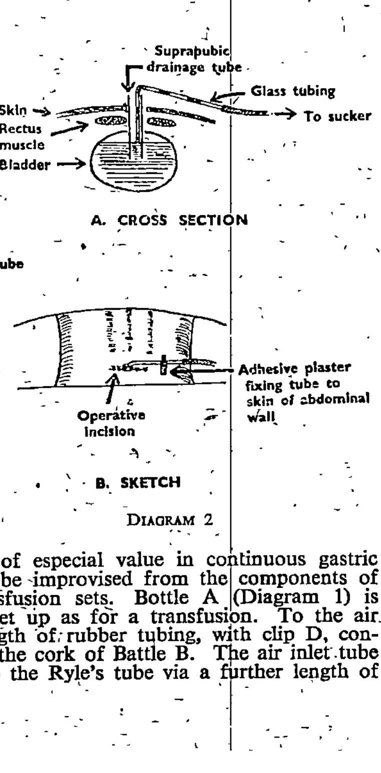

Diagram 2

Wangensteen's sucker is of especial value in continuous gastric aspiration and can readily be improvised from the components of two standard M.R.C. transfusion sets. Bottle A (Diagram 1) is filled with tap water and set up as for a transfusion. To the air inlet tube is attached a length of rubber tubing, with clip D, connected to the short tube in the cork of Battle B. The air inlet tube of Bottle B is connected to the Ryle's tube via a further length of tubing. The tubing from Bottle A to the drip chamber is continued into the receiver, C. When both clips are open, water flows from Bottle A into Receiver C. The vacuum created above the water in A is transmitted to Bottle B, which acts as a reservoir for the aspirate drawn into it: the character and volume of this material can be seen at a glance. When emptying Bottle B, or filling Bottle A, both clips should be closed. One important detail is that the tubing in Receiver C should dip below water—otherwise air will be sucked back into Bottle A at intervals, and the negative pressure temporarily lost.

This apparatus was first assembled one night at 1 a.m. in a space of fifteen minutes and maintained continuous and satisfactory gastric suction for three days. This success was repeated in a number of adult cases and also on a six-months-old infant with severe post-operative vomiting.

The sucker can also be used, in conjunction with the second device, for suprapubic drainage. All that is needed is a piece of quarter-inch glass tubing, 10 in. long, having arms 2 and 8 in. long set at an angle of 80 degrees to each other.

At operation, rubber tubing with an internal diameter of at least half an inch is used as the suprapubic drain, and is allowed to project three-quarters of an inch above the skin. When the patient returns to the ward, the short arm of the sterilized glass tubing is placed in the lumen of the drainage tube and the long arm is strapped to the abdominal wall and connected up to the sucker (Diagram 2). The urine which fills the suprapubic tube is sucked off through the glass tube at a level below that of the bladder wall as the patient lies in bed. It can never, therefore, reach a level at which it can soil the skin or seep up around the drainage tube. The patient is kept dry and comfortable and his wound heals rapidly.

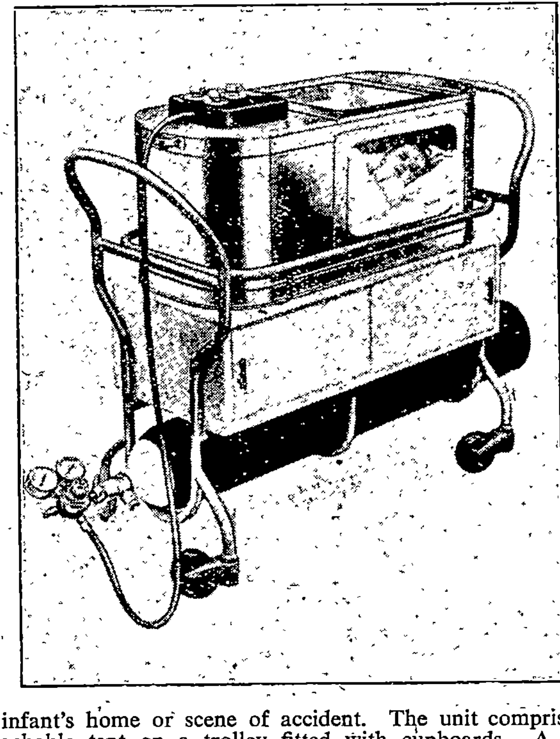
The best dressing was found to be plain gauze over the wound and fluffed cotton-wool around and over the tubes, the whole being held in position by a many-tailed bandage.

It is a pleasure to acknowledge the advice and encouragement given me by Prof. J. Paterson Ross and Sister E. C. Hall in the development and maintenance of these devices. I have to thank the D.D.M.S., Paiforce, for his permission to submit this note for publication.

MOBILE OXYGEN TENTS

The 24-hour rental service for the dispatch of all types of modern oxygen tents to hospitals and private patients, which has been available in London and the Home Counties during past years from Oxygenaire, Ltd., 8 Duke Street, W.1, has been extended to three new areas. Oxygenaire tents can now be delivered on loan for urgent cases in these areas by telephoning at any time of the day or night to the following: Oxygenaire (Bristol) Ltd., Abson 81; Oxygenaire (Birmingham) Ltd., Calthorpe 1737; Oxygenaire (Manchester) Ltd., Sale 5218.

The accompanying illustration represents the latest design in infants' mobile oxygen tents for transportation by ambulance to infant's home or scene of accident. The unit comprises a detachable tent on a trolley fitted with cupboards. A high oxygen concentration can be rapidly obtained from a control panel fitted with a circulation control, de-oxygenator, and extraction control. The temperature of the tent can be regulated from a compartment for hot-water bottles.



WORK OF A FIELD AMBULANCE IN THE BATTLE OF NORMANDY

BY

F. S. FIDDES, M.B., Ch.B.

Major, R.A.M.C.

The title of this article has been chosen for convenience rather than accuracy, for it is proposed merely to give a statistical review of the cases handled in the advanced dressing stations successively established by the headquarters company of a field ambulance during the period July 1 to Aug. 24, 1944. It is not intended to discuss the tactical and administrative considerations which are so important in the field, or to describe the layout adopted or the scope of medical work attempted. The arduous and often gallant work of the bearer companies will receive no more than this passing mention, as will the work of the ambulance drivers, whose scarred vehicles bore witness to their hazardous employment. It is gratifying, however, to be able to record that in all respects the training and planning of the waiting years were proved sound and well adapted to meet the strain of actual war.

The period under review has been arbitrarily entitled the Battle of Normandy. It began with the earliest attempts to break out of the bridgehead, which, though still small, was well established by the end of June. It included a spell of very bitter fighting in the vicinity of Caen and on the Orne River. It ended with the virtual closure of the Falaise-Argentan gap and the liquidation of the German Seventh Army.

During the 55 days thus covered an advanced dressing station was fully established and open on 45 days, on seven successive sites. The remaining 10 days are accounted for by three days in rest and seven days occupied in movement or in harbouring during movement. The total number of cases handled was 2,641, of which rather more than half (1,476) were attributable to battle conditions (battle wounds, battle accidents, and battle "exhaustion" cases), and rather less than half (1,165) were of incidental origin (accidental injuries, sick and dental cases). The average number of cases dealt with while in action was therefore 55 to 60 a day, the greatest number on any single day being 250.

With the personnel and equipment available, it is considered that 250 cases in one day is about as many as can be handled by the headquarters company of a field ambulance without loss of efficiency, especially if that total includes a high proportion of battle casualties and if resuscitation is being carried out in the cases which require it. This is not to say that greater numbers have not been dealt with within 24 hours with the assistance of reserve bearer company personnel, but as a general statement it is probably correct. Seriously and extensively injured men need handling with skill and care, and adequate first-aid measures in such cases occupy a considerable time. That the expenditure of time involved is worth while was repeatedly made obvious by the extraordinary improvement in the patient's general condition after careful manipulation, adequate dressing and splinting, ingestion of fluid, and the short rest, quite apart from the beneficial effects of transfusion in those cases in which it was considered necessary.

Type of Casualty and Disposal

The categories into which the various "casualties" fall and their disposal are summarized in Table I.

TABLE I.—*Type of Casualty and Disposal*

Type of Casualty	Died	To F.D.S. for Resuscitation	To C.C.S.	To F.D.S. for Minor Cases	Returned to Unit	Total
Battle wounds ..	12	83	792	72	64	1,023
Battle accidents ..	—	2	62	13	14	91
Battle exhaustion	—	—	—	313	49	362
Accidental injuries	—	1	91	28	78	198
Sick	—	—	115	291	298	704
Dental cases ..	—	—	—	—	263	263
Total ..	12	86	1,060	717	766	2,641

From Table I it will be seen that 1,863 cases required evacuation. The running time taken by ambulance cars to reach the C.C.S. varied at different stages of the advance from 1 hour to 3 hours, or even more by night or when much other traffic was on the road. In general, however, the time was relatively short, and if the patient could be dispatched in satisfactory condition one had little fear of undue deterioration during transport. The motor ambulance convoy service was excellent. When a Divisional field dressing station was established as a resuscitation centre it was normally sited close to or even alongside the advanced dressing station. Consequently there was no loss of time in the evacuation of those grave cases which needed transfusion and other resuscitation measures. Where no such centre was available, resuscitation and transfusion were carried out in the A.D.S.

Evacuation of exhaustion and minor cases to the Divisional F.D.S. established for their reception was carried out in field ambulance cars, and presented no real problems. If the necessity for ambulance cars in the forward area precluded their availability for such rearward evacuation it was usually possible to borrow from the field ambulance in reserve for this latter purpose.

Battle Casualties: Wounds

Actual battle wounds provided the most numerous type of casualty dealt with, totalling just over a thousand, of whom approximately 50% were lying (stretcher) cases and 50% walking (sitting) cases. This differs from the "traditional" expectation of 40% lying and 60% walking, but is in agreement with the previous recorded experience in this war. The increased incidence of lying cases is possibly due in part to the greater disabling power of modern missiles, as has been suggested. But another explanatory factor may be found in the improved conditions of evacuation from the forward areas and the lower casualty rate as compared with the war of 1914–18. The use of carriers and jeeps, and the ability of small ambulance cars to maintain a good service from the regimental aid post, have made long hand-carrying fairly exceptional and ambulance accommodation fairly liberal. Consequently a certain proportion of cases have rightly been made stretcher cases who in other circumstances might necessarily have been encouraged to remain as walking cases, at least till the dressing station was reached.

The total of 1,023 battle-wound cases was made up as shown in Table II.

TABLE II.—*Incidence of Battle Wounds*

British military	908
German military	93
French civilian	22
Total	1,023

The majority of the German military wounded were brought in during the later stages of the period under review. Prior to that, the taking of German wounded was comparatively rare, so that it must be supposed that their collection and evacuation was proceeding satisfactorily. In the later stages, however, German forward medical posts were overrun before their occupants could be evacuated, and a number of German wounded were brought in who had lain out for days and were consequently in bad condition. The only cases of established gas gangrene seen in the A.D.S.—three in number—were in German wounded.

TABLE III.—*Disposal of Battle-wound Cases*

Dead or dying on admission	12
To resuscitation centre (Div. F.D.S.)	83
To C.C.S.	792
To F.D.S. for minor cases	72
Returned to unit (or home, in case of civilians)	64
Total	1,023

The total recorded in Table III as sent to C.C.S. included 30 cases given special resuscitation measures in the A.D.S. before evacuation, making the total of cases requiring resuscitation (i.e., Group I cases) 113—say 10 to 12%. Fourteen cases were transfused with plasma in the A.D.S., and approximately 50 out of the 83 cases transferred to the resuscitation centre were transfused there. All such cases were evacuated to the C.C.S. with continued transfusion in progress. It can reasonably be assumed that a certain proportion of the other cases would be considered to require transfusion at the C.C.S. before, during, or after surgical treatment; and if this assumption is agreed, then the present series of figures seems to conform fairly well with the general proposition that has been made—namely, that 10% of battle casualties need transfusion at some stage in their evacuation. Perhaps the percentage should be slightly higher.

There were many cases of multiple wounds, of course, but where one wound was obviously major in comparison to the remainder, the case has been classified according to the location of that major wound (Table IV). Only two of the penetrating chest wounds and two of the penetrating abdominal wounds are recorded as not being

TABLE IV.—*Location of Battle Wounds*

Site of Injury		Severe	Mod. Sev. or Slight	Total		%	% Anticipated
Head		32	37		69	6·7	5
Face	Facio-maxillary	7	47	54	80	7·8	4
	Eyes	2	10	12			
	Ears (blast)	2	12	14			
Neck		3	14		17	1·6	
Chest	Penetrating	23	2	25	55	5·4	5
	Non-penetrating	2	28	30			
Abdomen	Penetrating	22	2	24	40	3·9	5
	Non-penetrating	2	14	16			
Back		11	53		64	6·3	—
Upper limbs	Above elbow	26	116	142	288	28·2	30
	Elbow	4	16	20			
	Below elbow	20	106	126			
Lower limbs	Above knee	51	131	182	354	34·6	36
	Knee	8	39	47			
	Below knee	26	99	125			
Multiple injuries		13	38		51	5·0	—
Blast injuries		3	2		5	0·5	—
Total		257	766		1,023	100·0	—

severe. Even such a small number calls for explanation, however, where penetrating wounds of that nature are concerned. Unfortunately, the reasons for considering them as being only of moderate severity were not recorded and cannot be recalled by the medical officers concerned. The incidence of wounds of the back and buttocks (the latter included among the wounds of lower limbs—above knee) might seem surprisingly high. The explanation is that mortar and air-bursting shells inflict a high number of such injuries on soldiers lying prone on the ground or even in slit-trenches or ditches.

For interest and comparison, the final column of Table IV shows, where comparable, the anticipated percentage location of wounds. These figures were used as a basis for training and preparation, and are themselves based mainly on last-war statistics, as very little corresponding information has been found available regarding battle casualties in this war up to date. There is a fairly close correspondence. Moreover, it will be noted that where the actual incidence of wounds is higher than that anticipated, it is in sites where the incidence of severe cases is also high—head, face, and neck, chest, and abdomen. As the figures upon which the anticipated incidence was based were chiefly those furnished by base and home hospitals, the correspondence would have been closer if the mortality of such cases *en route* had been allowed for—i.e., if the anticipated incidence in the field of such severe cases had been slightly increased and the incidence of leg and arm wounds correspondingly reduced. If, after the war, the statistics from our base and home hospitals show a similar discrepancy it will be interesting confirmatory evidence that the severely wounded man in this war has in fact a better chance of survival than his predecessor of 1914–18.

Table IV shows that approximately 25% of the total were severe cases. It is possible, however, to indicate degrees of severity in greater detail, and to correlate these with ultimate disposal, as has been done in Table V. This, while admittedly a general approximation, is useful to bear in mind when planning the accommodation and routine of an A.D.S., and; though it is hoped that the necessity for such planning will soon be past, it is included for that reason.

TABLE V.—*Severity of Cases and Disposal*

Dead or dying	1%	
Very severe	12%	For resuscitation
Severe	12%	To C.C.S.
Of moderate severity	50%	
Relatively slight	12%	
Slight	12%	To F.D.S. for minor cases, or R.T.U.
Trivial	1%	

The important lesson to be drawn from Table V is that one case in four or five will be severe or very severe, and will require skilled handling by possibly two or three orderlies and perhaps the personal attention of a medical officer for a very appreciable period of time—anything from 10 minutes up to an hour. These are the cases which stand in greatest need of early and skilled first aid, and these are the cases which tend to suffer most during rush periods or if the daily total rises to undue proportions. Hence the earlier remarks on the desirable maximum of 250 cases a day for an A.D.S.

The complete absence of wounds from aerial bombing in Table VI will be noted as a reminder of the great part in the campaign played by a dominant Air Force. Shell wounds—mortar or H.E.—accounted for three-quarters of all battle wounds seen. High-explosive shells claimed the greatest number of victims overall; but if infantry battalions alone are considered, the relative frequency of H.E. and mortar wounds would be reversed. The very high proportion of H.E. and mortar wounds reflects, of course, the relatively static, bitter to-and-fro fighting which occupied a considerable part of the period under review. Proportions may vary somewhat with altered circumstances, but it is unlikely that any of the other agents mentioned in Table VI will equal the mortar and the field gun. The aerial bomb is their only possible rival if one excludes chemical warfare and the possible secret weapons of the future

TABLE VI.—*Causative Agent*

Shell wounds	H.E.	310		692
	Mortar	251		
	?	131		
Gunshot wounds	M.G.		62	171
	Rifle		26	
	Pistol		6	
	?		77	
By mines and booby traps				34
„ grenades				26
Effects of H.E. blast				19
Burns (from phosphorus grenades or direct hits on vehicles)				6
Wounds of uncertain origin (mostly H.E. or mortar)				75
Total				1,023

Battle Accidents

The term "battle accident" has been reserved for those injuries whose occurrence was linked directly with battle conditions (Tables VII and VIII), such as a gunshot wound due to the accidental discharge of a weapon when creeping through a hedge during an attack, or a sprain or laceration due to a fall in advancing over rough ground in the dark or to a hasty jump into a slit-trench to avoid enemy fire. The total of such injuries dealt with was 91, all British military, of which 9 were severe injuries. In 9 cases vehicles were involved. The cases were disposed of as follows: To C.C.S., 64; to F.D.S. for minor cases, 13; returned to unit, 14.

TABLE VII.—*Location of Injuries in Battle Accidents*

Site of Injury		Severe	Mod. Sev. or Slight	Total		%
Head		3	2		5	5·5
Face		0	3		3	3·3
Chest		0	3		3	3·3
Abdomen		1	2		3	3·3
Back		0	2		2	2·2
Upper limbs	Elbow and above	0	5	5	29	31·8
	Below elbow	2	22	24		
Lower limbs	Knee and above	0	17	17	42	46·2
	Below knee	1	24	25		
Multiple		2	2		4	4·4
Total		9	82		91	100·0

TABLE VIII.—*Battle Accidents: Nature of Lesion*

Sprains, bruises, and crush injuries	40
Gunshot wounds	16*
Abrasions, cuts, and lacerations	13
Fractures (not associated with gunshot wounds)	12
Burns	10
Total	91

* Includes 6 cases in which the Sten gun was the weapon concerned.

Accidental Injuries

In a large mechanized army, operating in a congested and battle-ravaged area, a high incidence of accidental injury might well be anticipated (Tables IX and X). The total of 198 such cases treated is therefore surprisingly small, especially when it is added that only 9 of these were severe injuries, and—most surprising of all—in only 7 cases were mechanical vehicles involved. In explanation it should perhaps be remembered that the field ambulance was concerned almost entirely with soldiers of a first-line fighting formation—that is to say, with young men of high medical category, hardened and trained for warfare—and among such the proportion of "accident-prone" individuals who survive the training is probably small.

TABLE IX.—*Location of Accidental Injuries*

Site of Injury		Severe	Mod. Sev. or Slight	Total		%
Head		0	7		7	3·6
Face		0	12		12	6·1
Chest		1	7		8	4·1
Abdomen		1	3		4	2·0
Back		0	4		4	2·0
Upper limbs	Elbow and above	2	6	8	75	38·1
	Below elbow	1	66	67		
Lower limbs	Knee and above	0	24	24	86	43·1
	Below knee	2	60	62		
Multiple		2	0		2	1·0
Total		9	189		198	100·0

The disposal of accidental-injury cases was as follows: to C.C.S., 92; to F.D.S. for minor cases, 28; returned to unit, 78. The high proportion of cases returned to unit is due to the fact that the total includes many such accidents as could be dealt with by primary suture or other initial treatment in the A.D.S. and subsequent treatment in unit lines, or by daily attendance at the A.D.S. for a relatively short period.

TABLE X.—*Accidental Injuries: Nature of Lesion*

Sprains, bruises, and crush injuries	54
Gunshot wounds	52
Burns and scalds	45
Abrasions, cuts, and lacerations	38
Fractures (not associated with gunshot wounds)	9
Total	198

The total of 52 gunshot wounds includes 10 cases in which the Sten gun was the weapon concerned. The incidence of Sten gun accidental injuries, and some slight knowledge of the weapon itself, suggest that it is rather more "chancy" than other small arms in common use, and more likely to cause accidental injury in circumstances not involving carelessness or stupidity. In 15 to 20 cases of "accidental" G.S.W. the suspicion of possible self-infliction was aroused.

It will be noted that burns and scalds, rare as battle wounds or battle accidents, occupy quite a high place among accidental injuries. These accidental burns were mostly of hands and/or face, and fortunately few were severe. In spite of repeated warnings and injunctions the cause was almost invariably carelessness in the use of petrol cookers, and it would seem that the British soldier simply cannot be brought to regard petrol with due respect.

Battle-exhaustion Cases

"Exhaustion" is the term currently employed to cover all psychiatric casualties while they are in forward areas. In the total of casualties under present consideration 362 such cases are included, varying widely in severity and type; for the term is one of convenience, and the proper sorting and full psychiatric diagnosis of "exhaustion" cases were ultimately decided by the psychiatrists. From the A.D.S. 313 cases were evacuated to the F.D.S. established for their disposal, and 49 were returned to unit. The great majority of those evacuated did in fact rejoin their units also, after a relatively short absence. The total of such cases may appear high, but is probably no greater than was anticipated by those with knowledge of previous campaigns. The really high incidence was encountered in the earlier stages of the battle, and it is interesting to speculate on the various factors possibly involved: the standard of officering, the standard of discipline, the severity or the duration of strain, age group and battle experience, the role of the unit—attack or defence—inherent psychopathic inferiority, nationality or race, domestic or other difficulties, and so on. Much has already been written on the subject, and no doubt much more will still be written, but not in the course of this article, which states merely the incidence of exhaustion cases for comparison with other types of casualty.

Sick

The total sick dealt with by the A.D.S. was 704, of whom 681 were British military cases and 23 were French civilians. The disposal of sick was as follows: to C.C.S., 115; to F.D.S. for minor cases, 291; returned to unit, or home in the case of civilians, 298. Obviously, therefore, much of the sickness was of a minor nature, and the general health of the British military personnel was in fact very satisfactory indeed.

TABLE XI.—*Incidence of Diseases*

Medical		
Alimentary system:		
Acute infective gastro-enteritis	206	256
Other diseases	50	
Skin conditions:		
Various	100	127
Insect bites	27

,, (fresh)	1	
Syphilis (fresh)	1	
,, (continuation treatment)	34	
Malaria	5	
Infective hepatitis (?)	4	
Diphtheria	1	
Chicken-pox	1	
Rubella	1	
Miscellaneous		55
Surgical		
Major surgical conditions		18
Minor ,, ,,		60
Total		704

The presence in Table XI of 206 cases of acute infective gastroenteritis, mostly occurring within a fortnight, is a reminder of the ever-present menace which epidemic disease is to an army in the field. Fortunately the clinical form of the disease was relatively mild and of short duration. For the other alimentary complaints dealt with—chiefly mild gastritis—the change of diet and, occasionally, dietary indiscretions could usually be held responsible. Constipation was fairly common, with haemorrhoids as an occasional sequel.

The skin diseases were chiefly impetigo, boils, and tinea cruris or pedis, the latter proving very disabling in a number of cases. The lack of fresh food, the frequent difficulty of washing and bathing, and a probably inadequate fluid intake may have been factors in the production of skin disease, although the figures are not alarming. On the subject of bathing, it is suggested that the British army mobile bath facilities could be greatly improved. It should be stated, however, that only 4 cases of louse infestation were treated.

Insect bites were very common and troublesome, and the total of 27 included in Table XI refers only to those cases in which gross oedema, infection, or lymphangitis and adenitis were present. The main reason for referring to them is to suggest the desirability of an effective anti-insect cream or lotion for military campaigns even in temperate climates.

The incidence of fibrositis, lumbago, etc., is probably low, considering the conditions under which the troops lived in an unusually wet July.

The total of pyrexia of uncertain origin includes the usual quota of febrile coryzas and "influenzal" conditions, but serious diseases of the respiratory system were rare, comprising only two cases of pleurisy with effusion, one of tuberculous haemoptysis, and one other case of suspected active pulmonary tuberculosis.

The eye conditions treated were chiefly conjunctivitis and blepharitis—associated with driving in much dust—foreign bodies, and occasionally corneal ulceration. Eye lotions were always kept available for unit drivers, and also made available for visiting dispatch riders and vehicle drivers.

Aural conditions were mainly otitis externa, wax in the meatus, and Eustachian catarrh. Fresh otitis media was not seen, but several chronic suppurative cases came to light which had not been downgraded and eliminated from the units before embarking.

The case of diphtheria occurred in a French civilian; the chicken-pox was in a soldier who believed he had contracted it in a civilian house; while in the case of rubella no probable contact could be discovered. Continuation treatment for syphilis in the forward areas was a new departure and proved satisfactory, marked irregularity in attendances being uncommon, and invariably the result of circumstances rather than negligence. Few malaria recurrences were seen, but in some formations with previous service in Sicily and Italy conditions were otherwise.

The major surgical conditions seen were acute and subacute appendicitis, one case of testicular torsion, hernias, and badly infected hands. The minor surgical conditions were mainly carbuncles and less severely infected hands.

Dental Cases

The 263 dental cases seen included a disproportionate number of L. of C. troops, whose dental fitness before embarkation was obviously lower than that of the more regularly "vetted" infantry battalions. Broken denture replacement worked fairly satisfactorily, having in mind the difficulties due to movement of units, etc. The total recorded does not of course include the battle wounds of a facio-maxillary nature, in connexion with which the valuable advice and co-operation of the dental officer were normally sought.

Conclusion

These figures, and the comments thereon, have been compiled as opportunity afforded during the swift and dramatic sweep through France and Belgium which followed the Battle of Normandy. With the waterways of Holland and the defences of the Reich still ahead, the work of the field ambulance is not yet ended. But the figures from that early decisive period in Normandy form a completed chapter in themselves which may be found of general interest. For his encouragement and permission to submit this article for publication I am indebted to Lieut.-Col. M. DeLacey, R.A.M.C., and if the article had been of enough merit to justify a dedication, that dedication would undoubtedly have been to the "other ranks" of the Corps with whom it has been such a pleasure to be associated in action, and whose skill and co-operation with the medical officers have made possible what we believe to be a fairly satisfactory record of service.

SALMONELLA INFECTIONS

The micro-organisms classified as *Salmonella* strains comprise a bacteriological group allied to typhoid and dysentery bacilli but culturally and serologically distinct. Their wide distribution and the variety of diseases they cause in man and animals make them of great practical importance. All the members of the group seem to be true parasites, pathogenic to man or to animals or to both man and animals, and they do not occur anywhere as harmless saprophytes. It is true that they have been isolated from certain internal organs, such as the mesenteric glands and spleen of apparently healthy pigs—by Scott in this country and by Ruben, Scherago, and Weaver in the U.S.A.—but the probable explanation is that they are survivals from earlier infections of these pigs. The same applies to rats and mice, and it has been repeatedly shown that if a large series of rats is examined living *Salmonella* strains can be isolated from a small percentage of them. Salmonella infections of rats and mice, with a heavy mortality and with carrier survival in a proportion, are fairly common. Salmonellas are responsible for many animal epidemics and affect many animals, including pigs, cattle, and especially calves, horses (with a strain not pathogenic to man), rabbits, guinea-pigs, rats, mice, dogs (occasionally), and a variety of birds, including fowls and ducks. The strains affecting hens are nearly always either *S. pullorum* or *S. gallinarum,* types hitherto regarded as entirely non-pathogenic to man. Recently, however, there has been some evidence that *S. pullorum* may occasionally be a cause of human illness. Ducks, on the other hand, are affected with several *Salmonella* strains pathogenic to man, and it is well attested that infected ducks' eggs have been responsible for many outbreaks of food-poisoning. Sheep are only rarely attacked by any salmonella infection.

With such widespread infections in domestic animals and animals having access to man, opportunities for transference to man are many, and *Salmonella* strains are of much importance as a cause of human disease. These infections fall clinically into three groups. One form is long-continued fever of the enteric type, often indistinguishable clinically from typhoid fever, and diagnosed only by serological and bacteriological methods: paratyphoid fever is the recognized example. A second type is that of severe acute gastro-intestinal irritation with rapid onset and comparatively short duration, which we recognize as a common variety of food-poisoning. It occurs in the form of outbreaks associated with the consumption of a particular food infected with a living *Salmonella* strain. In paratyphoid fever the incubation is long, but in this second type it is usually 12 to 24 hours. Until comparatively recently these were the only clinical varieties recognized, but over the past few years there have been many cases reported of infections with a *Salmonella* strain resulting in a septicaemia with a high mortality. Usually they appear as isolated cases, not in outbreaks, with no indication as to the source of the infection and without demonstrable relationship to other cases. The infection probably takes place through the intestine, but for unknown reasons blood infection occurs and general infection and localization in different organs. Thus the clinical manifestations are varied. S. Bornstein,[1] in a review of the salmonella problem, refers to clinical cases of endocarditis, meningitis, osteomyelitis, and other more rare conditions.

In connexion with these clinical varieties two points naturally arise—i.e., whether each is associated with different *Salmonella* strains, and whether in the same outbreak the clinical manifestations are all of one kind, or mixed. *Salmonella* types are identified only to a small extent by cultural and pathological characteristics, and mainly by elaborate serological classification. Many new strains are identified each year, and there are over 100 different types. Their identification is not just a game for the bacteriologist, but supplies two points of practical value. One fact which emerges is that certain salmonellas tend to become selective as regards both their hosts and the type of disease which they cause. The most widely distributed strain of all—*S. typhi murium*—is promiscuous in its hosts and widespread in its manifestations. At the opposite pole, *S. paratyphosum B* is parasitic only to man, and for the most part causes only paratyphoid fever. As in all salmonella infections this behaviour is not absolute, for occasionally gastro-intestinal symptoms may predominate and there are a very few genuine records of this organism appearing in hosts other than man. Again, *S. pullorum* is a common infection in hens but harmless to man, with possible but rare exceptions. In paratyphoid fever there is a blood infection with long-continued fever; human carriers, especially temporary carriers, are common, and, with clinically unrecognized cases, are the main methods of spread. In food-poisoning from other types the opposite occurs: the attacks are short, there is no blood infection (except in fatal cases), the clinical picture is acute gastro-intestinal irritation, and in general the bacilli are rapidly eliminated after a few weeks; only two or three chronic carriers have been recorded in the literature. The type of organism does, to some extent, therefore, affect the clinical manifestations, but there is a good deal of overlap. Type differentiation is also of use in relation to the distribution of salmonellas in various animals. A number of examples have been given already, but a further illustration is *S. enteritidis* Dublin. This strain is a common cause of infection in calves and cows, and correspondingly has been responsible for a number of milk-borne outbreaks, almost all of the acute gastro-intestinal type.

A consideration of these facts throws much light upon the methods of spread of salmonella infections and enables us to devise measures of control. In all cases the vehicle is infected food, apart from case-to-case infection in paratyphoid fever. For example, in a study of 40 outbreaks of paratyphoid fever Savage[2] reported 31 from infected food (cream products 16, milk 8, ice cream 2, other foods 5), 2 spread by water (and 1 was watercress), 3 from case-to-case infection, and 4 not ascertained. Outbreaks of the food-poisoning type always result from the consumption of salmonella-infected foods, especially made-up and man-handled foods.

---

[1] *J. Immunol.*, 1943, **46**, 439.

When the actual path of the infection from the salmonella source to the food is examined clear differences emerge. In paratyphoid fever the human carrier is either a chronic carrier, as is so common in enteric fever, or, more usually, a temporary carrier or an unrecognized ambulant case. It is useless to look for an animal carrier, because the paratyphoid bacillus does not infect animals. In food-poisoning of salmonella type it is of little value to look for a human carrier (apart from a case connected with a recent outbreak of food-poisoning), for persistent carriers are of great rarity. On the other hand, the *Salmonella* strains which cause food-poisoning are all associated also with disease in animals, and this fact must be remembered when looking for the source of their introduction into food. The infection may be caused directly by eating the flesh of an animal suffering from a salmonella infection, through milk drawn from a cow so suffering, from infected ducks' eggs, or most commonly from sound food infected indirectly, as from faeces of rats or mice. In the control of salmonella infections their wide distribution must therefore be borne in mind. The control of carriers and unrecognized cases is of essential importance in paratyphoid fever. An attack on animal diseases associated with salmonella infections is a long-term indirect method, but not a particularly promising one, of attacking food-poisoning. In all types of salmonella infection the care and preparation of food along the lines of strictest cleanliness are likely to yield the best results. In particular, special attention is needed to prevent manipulated food from being kept, before consumption, at temperatures which allow multiplication of *Salmonella* organisms. Again and again it has been shown that a particular food—such, for example, as ham or a made-up dish—has been eaten fresh without harm, while the same food kept for a number of hours at a moderate temperature has become toxic and its consumption has set up a severe outbreak of food-poisoning. Outbreaks of food-poisoning are especially frequent during the hot months of the year.

SIR WILLIAM GOWERS, 1845–1915

This is the centenary year of the birth of one of the greatest clinicians and teachers of clinical medicine of the nineteenth century, Sir William Gowers, born on March 20, 1845. At this time, when the future of medical education and of clinical medicine as we have known it are the subject of discussion so eager and so widespread, it is appropriate that we should turn back for a moment to consider what lessons one of the great clinicians of a past generation may yet have to teach us.

Few, alas, are left among us who saw Gowers in action as a clinical observer and teacher, but for these few the recollection of his clinical acumen, the fruit of a vast experience stored in his mind in orderly fashion and ready for instant recall, and of the inspiring quality of his teaching, is imperishable. There still lives among neurologists, handed down by those who were his colleagues or his pupils, a store of legends of his astonishing diagnostic skill and insight and of those forceful personal qualities in which the Victorian generation of physicians was so rich. The lesson of this is that at the very foundation of sound medical practice lies a wide and deep familiarity with its material: the patient and his illness. Nothing can replace this, nor can all the ingenuity of the laboratory, nor the penetration of the skiagram, provide a substitute for direct observation at the bedside, the clinic, or the consulting-room, and the unceasing contemplation of this direct experience. The complete physician, in fact, must be a connoisseur of clinical material, and not the least factor in the acquisition of this measure of skill and intuition is the careful and systematic recording of what has been observed. It is necessary to stress these points in view of the increasing reliance by doctors upon the special methods of the numerous and too autonomous departmentalists, and of the increasing tendency of the student to regard note-taking as a form of drudgery.

For those of us who have been born too late to savour the richness of the clinical medicine of some fifty years ago, we still have the published writings the great figures of the period have left us. In Gowers's famous textbook and in the numerous smaller manuals he wrote we find clinical medicine at its peak, and its recording in a fluent, logical, and vital English that we too often look for in vain in modern medical writing. To any one of Gowers's publications the professed neurologist of to-day may turn with profit to his knowledge, with keen pleasure to his feeling for words, if he be so happy as to possess one, and with some sense of a recapture of the personality of their author. Nor was Gowers purely the neurologist. In his later years he was pleased to recall the benefit he had received from the two years in general practice with which he began his medical career, and his was the first haemoglobinometer. His writings, too, abound in evidence of a broad and balanced knowledge of clinical medicine in all its aspects. It is indeed largely to Gowers and his contemporaries in neurology that we owe it that neurology is still rooted in general medicine, and thus finds it unnecessary to-day to claim a special place for itself in the medical curriculum.

In medical literature we have our English classics, but we regard them too little. Among them the published works of Gowers hold a distinguished place. Of particular value to those not specially interested in neurology are his published clinical lectures, which reveal a perfect balance of observation and of judgment, and a broad outlook that every clinical teacher might take as an example. During his lifetime his reputation was international, and his name is yet a household word among neurologists everywhere. Historical justice therefore requires that we should now recall him as one of the founders of modern British medicine.

---

BROMIDES AND BARBITURATES

From a recent review[1] of the literature on the neuropsychiatric effects of barbiturates and bromides a number of interesting points emerge. Bromides have a depressing action on the entire nervous system; and the same is believed to be true of barbiturates, though some authorities think they have a selective action on mid-brain vegetative centres. Their neurological effects are slightly different. Nystagmus, convulsions, and a positive Babinski are fairly frequent in cases of barbiturate intoxication, but they have not been reported in bromism. The disturbances of motility in cases of barbiturate poisoning have a cerebellar character and are different from the apraxic awkwardness observed in bromide cases. Curran considers that paraphasic speech disturbances, visual hallucinations "at a distance," confabulatory memory defects, and some other symptoms are of diagnostic value in the oblivion of bromide poisoning.

Drug psychoses make up a perceptible proportion—about 1%—of all admissions to mental hospitals in the U.S.A. They are about four times as common in men as in women, and the patients have usually begun to use the drugs in the third and fourth decades. According to insurance statistics barbiturates are responsible for about 6% of the suicides and 18% of the accidental deaths of policy-holders. In the U.S.A. morphine addicts who have been unable to get the drug have in some cases taken to using nembutal. Laboratory tests for bromides in the blood are simple and satisfactory; tests for barbiturates are in a less advanced state and do not appear to be of practical value.

The treatment of bromide intoxication consists in stopping the drug, forcing fluids, and giving sodium chloride. In the treatment of barbiturate intoxication of severe degree gastric lavage is followed by the administration of 30 to 60 grains of magnesium sulphate. Intravenous dextrose (5%) is recommended. Picrotoxin has been found valuable by many workers, and a 0.3% solution should be given at the rate of 1 c.cm. a minute until corneal reflexes reappear and the patient responds to powerful stimuli. It will have to be repeated at hourly or two-hourly intervals, and 3 to 6 mg. an hour will be required. One patient is recorded as having been treated in this way for 78 hours, receiving a total of 559 mg. of picrotoxin before he regained consciousness.

Although the dangers of barbiturate intoxication cannot be minimized, they are not now taken quite so seriously as they were before the war. A great majority of the fatalities must be due to suicide. The barbiturates are now very extensively employed, particularly in anaesthesia, as hypnotics, for the treatment of epilepsy, and in psychiatry for producing various degrees of sedation up to continuous narcosis. For these purposes they would prove in practice irreplaceable. Though they all belong to the same chemical family, they vary very widely in their physiological effects and can be employed for a great diversity of uses. It seems that the family is still a prolific one, and that further additions will supply us with drugs with new uses and with greater safety factors than in the past.

THE SCHIZOPHRENIC TESTIS

At the end of the last war Sir Frederick Mott found in the testes of schizophrenic patients histological changes which were for the most part interstitial in nature and ascribed by his critics to such conditions as chronic tuberculosis, from which many of Mott's patients died. It seemed impossible to get round this source of error until examination by biopsy was introduced. Hemphill, Reiss, and Taylor[1] have now reported on testicular biopsies in 90 schizophrenic patients and have compared them with the findings in a control series of 25 patients suffering from other forms of mental disorder. Over half the schizophrenics showed regressive changes, which were found in only three of the other patients, and they were known to be subjects of endocrine or organic disorder. The changes found by Hemphill and his colleagues are not those described by Mott, but consist of an atrophy chiefly affecting the tubules and their contents, with hyalinization of the basement membrane, arrest of spermatogenesis, progressive degeneration of epithelial elements, and eventual destruction of the tubule. Of all schizophrenics those with a paranoid form of psychosis were almost immune to these changes, which were found in their most advanced form in chronic catatonic and deteriorated patients, and in early cases. In his extensive genetic investigations of schizophrenia Kallmann[2] has reported much-reduced fertility in catatonic and hebephrenic patients, less reduction in patients with schizophrenia simplex, and normal fertility in paranoid schizophrenics. These clinical groupings correspond very closely with those of Hemphill, Reiss, and Taylor.

That advanced testicular changes may be found in patients with an early but a florid psychosis is of much interest; severe atrophy was found in one boy of 15 who had been ill for only a few weeks. This suggests that a biopsy may be of clinical value, for both diagnosis and prognosis. It is to be hoped that other workers will be encouraged to try it out.

The interpretation of these findings is far from easy. Hemphill[3] finds that the changes are not correlated with disturbance of the output of 17-ketosteroids, with age of patient or duration of illness, with bodily habitus or family history. There is no suggestion that any part of the aetiology of schizophrenia can be sought in these testicular changes. Hemphill considers that an endocrine imbalance with relative gonadotrophic failure may be responsible both for the tubular atrophy and, in a susceptible constitution, for the schizophrenia.

WAR AND THE AMERICAN BIRTH RATE

The war of 1914–18 did not affect the American birth rate to the same extent as that of many European countries. The rate for France fell from 18.8 per 1,000 to 9.5 in 1916; in Germany from 28.0 to 13.9 in 1917; in England and Wales from 24.2 to 17.7 in 1918; while in America the birth rate declined from 25.0 in 1915–16 to 22.4 in 1919. The casualties among the young males and the smaller number of potential parents born during the war had an effect on the birth rates of the belligerent nations which has not yet completely disappeared. The present war is likely to have a greater influence on the American birth rate than the last. Grabill[4] has given a short review of the recent trend and its possible course. Measures that may help to postpone a large fall in the American birth rate are the deferment of fathers from service for as long as possible, free maternity care for wives of Service men, family allowances, tax-exemption allowances for married couples and for children, and other benefits. Some of these were in operation before the war and were not brought in with the specific aim of encouraging the rearing of families. By 1932 the birth rate in the U.S.A. had fallen below 80 per 1,000 married women aged 15 to 44, the level necessary for the replacement of the population. The monthly birth rate fluctuated round the replacement level until the end of 1939, when the rate began to rise, with occasional peaks, until the end of 1942, when it was about 105 per 1,000 women. It then fell to 91 by March, 1944, though it rose sharply on two occasions in this period.

---

[1] Curran, F. J., *J. nerv. ment. Dis.*, 1944, **100**, 142.

[1] *J. ment. Sci.*, 1944, **90**, 681.

[2] F. J. Kallmann, *The Genetics of Schizophrenia*, New York, 1938.

[3] *J. ment. Sci.*, 1944, **90**, 696.

[4] *Amer. J. Sociol.*, 1944, **50**, 107.

The rise in the birth rate during the present war has occurred because of the abnormal marriage rate, and more women had their first or second child, but the birth rates of the third or more order of birth have steadily continued to decline. There has been, apparently, no change in the size of family, and the return of the marriage rate to a normal level will be accompanied by a fall in the birth rate. Grabill predicts, on the basis of potential fathers in the U.S.A., that the birth rate will steadily decline as more men are sent over-seas, and will reach a minimum of about 16.0 per 1,000; and that in the long-run the post-war trend will be again downward unless some fundamental changes occur.

Grabill notes some interesting coincidences between fluctuations in the birth rate and certain political and social events. The small fluctuations before the war tended to occur 9 to 10 months after some economic activity. The lowest rate in the period studied was that of September, 1933, 10 months after the 1932 election. A small peak occurred about 10 months after Roosevelt took office in 1933. In 1940 the rising trend of the birth rate was checked 9 months after the outbreak of the European war, and the rate remained almost stationary for several months. A small peak occurred in April, 1941, 10 months after the Selective Service Bill was introduced into Congress, and was followed by a larger peak with an interval of 10 months after the passing of the Selective Service Act. The birth rate passed through another stationary period 10 months after the passing of the Lend-Lease Act; the rate again began to rise 10 months after the signing of the Atlantic Charter. A very large rise occurred in October, 1942, 10 months after Pearl Harbour. Another large peak corresponded with the 10–11 months interval after Allied victories—Libya, Africa, Stalingrad, and naval victories over the Japanese—and after the minimum draft age had been lowered from 20 to 18 years.

THYMECTOMY FOR MYASTHENIA GRAVIS

The physiological researches of Harvey and his colleagues[1] have done much to explain the sort of disturbance which is present at the myoneural junction in patients with myasthenia gravis. After considering many possibilities they came to the conclusion that the most likely cause of the failure of cholinergic transmission from nerve to muscle in these cases was the presence of an unknown inhibitor substance released into the blood stream. The varying amounts of this substance would explain the varying clinical course of the disease, with its characteristic remissions. Gammon, Harvey, and Masland[2] produced evidence that this hypothetical substance might well be derived from the thymus gland. Thus a rational basis was offered for the empirical operation of thymectomy in myasthenia gravis.

Whatever the explanation of its beneficial results, the operation has been performed with increasing frequency in the past three years. In 1936 notable improvement occurred in the condition of a myasthenic patient after removal of a benign thymoma by Blalock.[3] After that Blalock and his colleagues determined to test the effect of total thymectomy in myasthenic patients without thymic tumours, and they published[4] the results in the first six cases in 1941. Blalock has now reported[5] upon the results in 20 operative cases, all of them severe myasthenics, many gravely ill with little chance of spontaneous remission. The daily dosage of prostigmine required before operation was always high—sometimes up to 900 mg. Only two of the patients had a thymic tumour. The interval after operation was from 5 months to 2 years 9 months. The results expressed in five groups of patients are very briefly that (1) 4 patients died after operation, one after 8 months; (2) 3 showed little improvement; (3) 5 were moderately improved; (4) 5 were considerably improved, one well able to continue without any medical treatment; and (5) 3 patients are "essentially well." The most phlegmatic reader of Blalock's paper will be impressed by the conservative interpretation he has put upon his results, for he has almost ignored the patients' protests of improvement and has set his standards firmly upon objective criteria. Of the second group he says: "The three patients state that they are somewhat improved, but I am inclined to believe that they are too optimistic." Even so the results are good and in 8 cases extraordinary; they establish thymectomy as a recognized form of treatment for myasthenia gravis. Churchill and Cope[6] have obtained results in 14 cases which are similar to those of Blalock, and, like them, they selected for treatment only greatly incapacitated patients. The severe cases of myasthenia in these two series were "bad operative risks," so the operation cannot be looked upon as severe for milder cases; the next step should be to extend it to them, with suitable controls. Blalock knows no way of predicting before operation which patients will be helped by thymectomy, although those with a benign tumour seem to benefit most. The chronic myasthenic does not appear to respond so well as the acute severely ill patient, and the bulbar symptoms do not clear up so readily as the general muscular fatigue and weakness. Further and larger series of cases will give the answer to many of the outstanding questions.

* * *

The Council of the B.M.A., at its meeting on March 21, received the report of the Negotiating Committee. After full discussion the Council decided to make a report with recommendations to a special Representative Meeting which will begin on May 3. The report of the Council is a confidential document in that it cannot be published, but it will be sent direct to every member of the profession, whether belonging to the Association or not. The Council decided to ask Divisions to make arrangements for an early meeting or meetings of the profession to discuss the report and instruct Representatives.

* * *

The twenty candidates nominated by the Council of the Royal Society for election into the Fellowship and elected on March 22 include Dr. Leonard Colebrook, honorary director of the research laboratories of Queen Charlotte's Hospital and now pathological consultant to the Army with the rank of colonel, and Prof. J. H. Gaddum, of the Chair of Pharmacology in the University of Edinburgh. Miss Marjory Stephenson, biochemist, and Mrs. Kathleen Lonsdale, physicist, are the first women to be elected F.R.S. in recognition of scientific work. Among the other new Fellows is Dr. H. Davenport Kay, director of the National Institute for Research in Dairying and at one time biochemist to the London Hospital.

Reports of Societies

FACTORS IN BLOOD COAGULATION

A discussion on blood coagulation was held at the Section of Experimental Medicine and Therapeutics, Royal Society of Medicine, on March 13, Dr. E. N. ALLOTT presiding.

Dr. R. G. MACFARLANE said that for more than fifty years blood coagulation had been an academic battleground for physiologists. The mystery of the conversion of a liquid into a solid had attracted many workers. It was known, of course, that two things might go wrong with coagulation of the blood: the blood might fail to clot when it was desired, and might clot when it was not desired, but very little could be done to prevent this.

The purpose of coagulation appeared to be to prevent loss of blood from the body. A defect in coagulation brought about a tendency to a rather peculiar haemorrhagic diathesis—a generalized tendency to prolong bleeding from any injured vessel. But blood coagulation was only a part, though an essential part, of the haemostatic mechanism. The primary factor was the contraction of the injured vessel. Secondary functions of coagulation were repair of wounds and warding-off infected areas. Blood coagulation might be a metabolic process which was going on all the time in the body, and the act of clotting merely an adaptation to meet a particular set of circumstances.

According to most theories clotting was the end-result of a series of separate events. Some which had been described, however, might well be artefacts produced by manipulation. The general theory of blood coagulation might be wrong altogether, and clotting might be a continuous process. Why did blood remain fluid in the vessel? In the first place, in the undamaged vessel there was no foreign surface to activate the kinase in the plasma. Whether coagulation occurred or not depended upon the rate of production of kinase and thrombin. If the rate exceeded that at which they were neutralized, coagulation took place.

The defects of the clotting system were shown first of all in haemophilia, in which the blood failed to clot in normal time. In this condition blood seemed to have the necessary fibrinogen and thrombin, but it would not clot. It had been shown that in haemophilic blood there was from five to eight times the amount of antikinase present in normal people. The treatment of haemophilia might be general or local. Substances which gave the best results were those of high kinase content: Russell viper venom was fairly successful. It was a sort of superstition that calcium deficiency was responsible for bleeding; but he had never observed it, and he did not know why so many people gave calcium when they suspected that the patient might bleed. There was a hereditary condition in which there was no fibrinogen at all, so that the blood was completely uncoagulable. He had seen two patients with this condition, both of them the offspring of first-cousin marriages. Another very rare condition was one in which the fibrolytic activity was such that the clots dissolved as soon as they were formed.

Burns were very different from abrasions in that they healed slowly. The superficial burn went on weeping and a solid scab was not formed. The delay in healing might be due to the absence of a natural covering of dried membrane. The Americans had made a plasticized fibrin membrane, which had the advantage from the point of view of a haemostatic dressing in that it was non-irritant and not likely to lead to any ill effects. The plasticized membrane could also be used as a dural substitute in brain operations, preventing the formation of adhesions between the brain and the scalp, which so often happened with other types of dressing.

Physiology of Vitamin K

Dr. H. SCARBOROUGH said that in the physiology of vitamin K the key part was played by the liver. It was in the liver that vitamin K was synthesized into prothrombin, which then passed out into the blood stream and took part in the coagulation process. Vitamin K, administered either orally or parenterally, must pass the liver before it could have any effect. Disturbances of vitamin K metabolism were reflected in a low level of prothrombin in the plasma. There was evidence that deficient intake of vitamin K was responsible for neonatal bleeding (it had been estimated that from 25 to 40% of neonatal deaths were due to intracranial haemorrhage). It was not entirely known why this bleeding tendency arose, but even in normal children plasma prothrombin was low at birth and fell after birth, particularly in premature infants. The administration of vitamin K to the mother could increase the prothrombin in the child, and this suggested that one of the causes of the neonatal bleeding was an impaired maternal contribution. A low prothrombin level in the child was related to toxaemic states in the mother.

Vitamin K could be administered to the infant. Indications for such administration were maternal toxaemia, prematurity, instrumental delivery, cases in which breast-feeding by the mother was impossible, and any cases in which an operation had to be performed on a newborn child. Many conditions could be prevented by routine administration of vitamin K to the mother. If the absorption of fat was defective some vitamin K was not absorbed and a haemorrhagic tendency might develop. Low levels of plasma prothrombin were found in some cases of disturbed intestinal motility—for example, in intestinal obstruction and long-continued diarrhoea and vomiting. These conditions led to a fall in plasma prothrombin, and treatment, controlled by the estimation of the plasma prothrombin level, was a matter of some urgency. The level also fell, often steeply, three or five days after a surgical operation, though the fall might occur within as short a time as a few hours. A normal prothrombin level before operation was no guarantee that post-operative haemorrhage would not occur as a result of the low prothrombin level. The level might fall rapidly after chloroform poisoning. In chronic liver diseases the fall was comparatively slow, and in liver disease, generally, very low levels were reached only rarely. Even a badly damaged liver was capable of synthesizing prothrombin. The level had no constant relation to the type of hepatic or biliary disease present.

Dr. Scarborough, speaking of dicoumarin as an anticoagulant, said it had lately been used in the treatment of threatened gangrene and of thrombo-lymphangitis; but the indications for it were not precise. Dicoumarin had rather a prolonged action, and even when it ceased to be administered its effect upon the prothrombin might continue for a week or a fortnight. It required very careful control by daily determination of the prothrombin. Its absorption was probably irregular, there was a considerable latent period before it became effective, and there was wide individual variation in the response to administration. It was certainly a toxic drug, and might give rise to haemorrhage difficult to control, though recent claims had been made that the prothrombin level resulting from dicoumarin administration might be lifted again by colossal doses of vitamin K. Dicoumarin increased the sedimentation rate; it was said to decrease clot resistance and firmness of clot in animals, and in many it produced capillary dilatation.

Finally Dr. Scarborough mentioned heparin, which could be used in all those conditions in which dicoumarin might find a place. It had advantages, but also disadvantages, making treatment difficult to control. Coagulation time might be prolonged by heparin to as much as two hours without dangerous effects occurring. The aim was a coagulation time of 15 or 20 minutes, but this was most difficult to attain, especially upon intravenous administration of heparin. Experiments were now being made with subcutaneous injection.

Discussion

The PRESIDENT said he had been interested in Dr. SCARBOROUGH'S rather pessimistic views on heparin. He agreed it was extremely difficult to assess its value. He mentioned the case of a patient with gross venous obstruction in the upper part of his body who was put on dicoumarin. There was little change in his prothrombin time, but three days after his last dose he had haematuria, bleeding from the gums, and epistaxis; the case eventually cleared up.

Dr. FREUND spoke of the value of calcium injections in the treatment of embolism. Mr. A. L. BACHARACH asked what was known about the changes in the intestinal flora during neonatal life. A good deal was known about the differences between human milk and cow's milk, but not everything, and one of the things not known was the effect, if any, on the intestinal flora. It would be interesting to compare the prothrombin time of breast-fed infants during the first fortnight of their lives with that of infants immediately put on the bottle. Different types of milk might have an effect on the intestinal flora, which was expressed in a different production of vitamin K. Major CLIFFORD WILSON described observations on soldiers with acute hepatitis, and said he had come to think that such phenomena as epistaxis were not connected so much with defective vitamin K absorption as with vascular phenomena associated with the hepatitis.

Dr. ELI DAVIS referred to a group of 500 cases in all of which some form of purpura was present and in which search was made for the vitamin K factor. In this number he had found only four definitely, and two others possibly, which gave strong evidence of prothrombin deficiency. Apart from this 1% of cases of purpura of all types, the general prothrombin index was between 85 and 100.

Dr. SCARBOROUGH, in reply, said he had not meant to suggest that the low prothrombin level was the sole cause of bleeding. He had studied 74 cases of scurvy and all had a prothrombin index of over 90. A low prothrombin index in an acute form of liver disease was quite unusual, and even when it did occur it was a fleeting manifestation.

Medico-Legal

BOGUS DOCTOR SENTENCED

Described by Judge McClure as "just an impostor," Richard Charles Vernon Grey (28) was sentenced to 12 months' imprisonment at the Central Criminal Court on March 9. After a second trial—the jury had disagreed at the first—he was found guilty of obtaining by false pretences £45 14s. from Dr. M. C. Irwin of Harringay, and sums of £26 14s. 6d. and £12 12s. from Dr. J. E. Price Watts of Chigwell.

Mr. Anthony Hawke (prosecuting) said Grey went to an agency which provided locumtenents and gave the name of a doctor who was on the *Register*. He said he was a bachelor of medicine and of surgery, and that he had held two medical appointments, one at Newcastle and the other at Manchester. As a result he obtained posts with a number of doctors. They, of course, accepted that he was fully qualified and on the *Register*. In no case was there any dispute about the quality of his work, which he carried out satisfactorily, but he would never have received payment for his services, nor such appointments, had the doctors concerned known the true facts.

Dr. Price Watts said that last September he required an assistant and engaged the defendant, Grey, who worked for him for a fortnight in October and a week in November. He received 12 guineas a week and all found. Grey was satisfactory and behaved as one would expect a doctor to do, and he was very interested in his work, but had he known that Grey was not a doctor he would never have considered employing him. He paid Grey for services rendered, but they were the services that he expected from a qualified doctor.

Dr. Irwin said that in November he required an assistant and engaged the defendant. "I thought he was a qualified practitioner and I arranged for him to do my Sunday duty and evening surgery. He was with me for the best part of two months and I paid him some £45. He showed skill, medical ability, and interest in his work."

Det. Sgt. L. Woolner said that on Jan. 26 he saw Grey and charged him with an offence under the Medical Act—namely, posing as a medical man. Grey replied, "There is not much use denying it." The defendant then made a written statement, and in this he explained that while serving with the R.A.M.C., from which he was discharged on medical grounds in June, 1942, he conceived the idea of becoming a doctor. He had had previous medical training, but did not wish to disclose the details. "From 1942 until October, 1944, I attended clinics in Manchester and London, where it was taken for granted that I was a medical student," he wrote, "and consequently I was allowed to attend lectures, out-patient clinics, and demonstrations. In October, 1944, I went to the agency and said I was a qualified practitioner, filled in an application form, and was given a selection of jobs to go to." Grey went on to explain in his statement that he was combining his work as a locumtenent with carrying on a consultant's practice as a psychologist in Harley Street. He did not give evidence in the witness-box. After the jury had found him guilty Det. Sgt. Woolner said Grey had six previous convictions. His first offence was stealing a doctor's doorplate, and the case was dismissed under the Probation of Offenders Act. In 1940 he was sentenced to three months' imprisonment for unlawfully representing himself to be a naval officer and for making a false statement with a view to obtaining an identity card. He now asked for three other cases of obtaining money by false pretences to be taken into consideration.

Correspondence

Shall We Nationalize Medicine?

SIR,—Lord Horder and I are old friends. Indeed, although he pretends to find something sinister in the word, I do not believe he would reject the idea of our being considered "comrades"! This being so he will not resent my selection for criticism of one or two assumptions and inconsistencies which found their way into his recent address at Cardiff (*Journal*, March 17). There is still need for clear thinking and free debate on such big issues.

First of all it is an assumption that State medicine must necessarily impose controls on the professional thought and actions of the doctor and spoil his age-long human relationships with his patients. There is no reason why "free speech on medical matters, free criticism of medical affairs, and free publication of scientific work" should not be preserved under a national system planned and organized to secure a more equitable distribution of health services, better co-ordination within those services, payment for those services from central sources, and universal contributions instead of directly from the patient's pocket, often at a time when he can least afford it.

The suggestion that the doctor should not be "political" implies a further assumption that he cannot be both a good doctor and a good citizen. One cannot develop one's functions fully as a doctor and a citizen without being interested in policies affecting the welfare of the community, and this is only another way of saying without "being political." Let us agree that it would be quite improper to mix politics with practice; and that it would be equally improper in the teaching of social medicine (which, like clinical medicine, has its scientific disciplines as well as its humanistic motives) to discuss political programmes for the solution of problems which can, and should, be as critically and dispassionately studied as bedside or laboratory problems. But it is surely wholly proper that doctors, when fitted and able to do so, should play a part in local government; that they should support parties which seem to them to work best in the national interest; and that they should sometimes occupy seats in the House of Commons—or even in the House of Lords! In these places what are they but politicians—left, right, or centre? The advocacy of 85% extraction flour—which you, Sir, actually refer to as the "political loaf" in your leading article of March 17—is surely political. Incidentally such advocacy requires State controls and opposes certain interests, and puts the people's health above individual "free choice."

And surely it is inconsistent to say that we doctors should remain "detached from political colour" and in the next breath to affirm that "many of us believe that to nationalize medicine is not only an unnecessary innovation but one which is unlikely to give the best results in medicine in this country. *If we find the public uncertain it is our bounden duty to convince it of this.*" Is it then non-political publicly to oppose a national service but political to support it? As Lord Horder reminds us, we stand convicted, with our legislators, for not having raised our voices more loudly about the environmental, nutritional, and other conditions which have maintained a vast and unnecessary amount of disease in our midst. The improvement of these conditions could certainly do more for national health than the extension and reorganization of the medical and other health services, but we are all entitled to speak according to our conscience, our experience, and our knowledge on either or both of these correctives.

I have advocated a full national medical service—to be introduced gradually with a system of five-year plans and appropriate priorities—because I sincerely believe it to be ultimately in the best interests of both the people and the profession of medicine. Until we have tried it, however, neither Lord Horder's assumptions nor mine can be proved the more correct. British medicine owes so much to him and he has done so much for his colleagues, students, and patients that his word commands a very great respect, but in a matter of prognosis he himself would not wish it to be considered final and authoritarian.—I am, etc.,

Oxford. JOHN A. RYLE.

Ludwig's Angina

SIR,—I have had a considerable experience of Ludwig's angina and have studied the literature and case reports for many years.

Oedema of the epiglottis is frequent, but I have not seen laryngeal obstruction. Tracheotomy instruments have always been ready when operating on these cases, but I have never had to use them. I believe that the reported fatalities are due to sudden heart failure. These patients are exhausted, ill, and suffer from severe toxaemia. Danish surgeons say the injection of novocain into the masseter and internal pterygoid muscles abolishes trismus.

If the U.S.A. Davis gag is used intubation is facilitated and the anaesthetic is continued during intubation. Moreover, the direct laryngoscope can be used with the Davis gag in position. Most surgeons agree that the abscess is found in the submaxillary gland fossa deep to the gland and superficial and deep to the mylohyoid muscle. In one case sepsis around an impacted wisdom tooth produced a lateral retropharyngeal abscess. A good exposure and access to the abscess was obtained by the Davis gag. All acute retropharyngeal abscesses should be opened with the use of this gag. Ludwig's angina can be drained by a large bow incision; the wound is opened widely by retractors and the abscess is found by dissection. When the abscess is found a finger is introduced to break down loculi and a small vertical incision is made to the lowest point of the abscess. A drainage tube is inserted for 48 hours only.

All these cases and deep abscesses in the neck so treated have made an uneventful and rapid recovery. I do not consider that the removal of the submaxillary gland or incision from the mouth into the neck is desirable or necessary. Also a drainage tube passed from the mouth into the neck wound causes discomfort, impedes feeding, and is unnecessary. —I am, etc.,

London, W.1. E. D. D. DAVIS.

Enteritis in Scotland

SIR,—A current outbreak of enteritis in Scotland is rousing public interest and causing comment in the Press and elsewhere. The ailment has been loosely described as "dysentery," but neither the pathogenic germs of this nor of other enteritic diseases have been isolated. The illness is mild, causing personal inconvenience and waste of industrial time rather than serious physical disability. In the absence of positive bacteriological evidence, may I put forward a theory based on personal experience?

Our wartime diet includes a much greater amount than formerly of tinned and other preserved foods, containing chemical substances, usually sodium nitrate, sodium nitrite, boric acid, and sulphur compounds. There must be few of us who do not ingest a certain amount of these chemicals weekly. It seems reasonable to suppose that a chance arrangement and superimposing of some of these common foods may give just that amount of cumulative irritation to set up an enteritis. In addition to tinned foods, one must not forget that preservatives are present in sausages and in "mince"—i.e., the uncooked minced beef sold by butchers—both very popular items of diet in Scotland, particularly in industrial areas. On at least six occasions during the past year a sudden enteritis, affecting my own household and others, was preceded by a meal of sausages which were fresh, palatable, and highly reputable.

It is a striking testimony to the purity of our food and water supplies that in the sixth year of war we are still without an epidemic of enteric infection. I would suggest that the amount of preservatives, in our home-produced food at least, might now be safely lowered for our national convenience.—I am, etc.,

Dyce, Aberdeenshire. MARGARET S. M. MCGREGOR, M.D.

Conservative Treatment of Duodenal Ulcer

SIR,—A recent statement by a speaker at the Royal Society of Medicine that perforated duodenal ulcers rarely recover without surgery prompts me to write concerning a conservative treatment of this condition.

I noticed when operating on perforated duodenal ulcers that often one had to remove an omental plug before suturing the perforation, and that often when assisting at a subtotal gastrectomy the patient had previously had a duodenal "leak" which had healed. After making these observations I decided to attempt a conservative treatment of perforated duodenal ulcer.

My small series of patients were six men—three between the ages of 20 and 30 and three between the ages of 60 and 65. On admission the clinical diagnosis of perforated peptic ulcer was in each case confirmed by a colleague. Immediately the diagnosis was confirmed morphine 1/4 gr. was given intravenously and an intravenous drip of 5% glucose in saline begun. Next the stomach was emptied by a wide-bored stomach tube, which was then removed, and a Ryle's tube passed nasally into the stomach and left *in situ*. The stomach was aspirated every half hour for the first 24 hours, every hour for the next 24 hours, and every 3 hours for the subsequent 24 hours. During the whole time the Ryle's tube was in use frequent mouth washes were given. For the first 24 hours morphine 1/4 gr. was given every 4 hours if abdominal pain returned, but I did not find it necessary to give it after that time. The intravenous glucose-saline was continued for the whole of the first 3 days, after which the patients were put on a Sippy diet, and in no case were there any ill effects and each patient made an uninterrupted recovery.

After a month each patient was examined radiologically and in each case the presence of a duodenal ulcer was confirmed. I am very grateful to Mr. G. W. Beresford, F.R.C.S., for his permission to carry out this method of treatment.—I am, etc.,

Southlands Hospital, Shoreham. E. W. BEDFORD-TURNER.

Incidence of Peptic Ulcer

SIR,—Sir Henry Tidy's interesting article on the incidence of peptic ulcer (March 10, p. 319) has social implications. The only factor I can think of which could affect the incidence of gastric ulcer in women about 1913 is that the period in question coincided with the cessation of tight lacing.

The increase in the incidence of duodenal ulcer perforations in men at the time of the worst London "blitz" may be accounted for by the greater exhaustion on the part of men than of women. Nearly all men in London at that time were doing frequent night duty in addition to daily work. Women constantly lost sleep too, but those with children at least rested when the children rested. And men smoked more—especially at night.—I am, etc.,

Leeds. R. A. MURRAY SCOTT.

Immunization against Tetanus

SIR,—There must have occurred to many practitioners in rural areas the desirability of inoculating substantial sections of the civil population with antitetanus toxoid. I refer particularly to workers on farms and small-holdings and those connected with horses, etc. How often do patients present themselves with injuries received in the course of their occupations, sometimes contaminated with dirt to a greater or lesser degree, and the problem always has to be considered whether or not to give antitetanic serum prophylactically. It is impracticable to do so in every case, and, as recent correspondence in the *Journal* has shown, tetanus not infrequently results from insignificant injuries.

Experience during this war has demonstrated the great value of inoculation of soldiers with antitetanus toxoid, and I write to suggest that the organization which must have been set up for the production of the toxoid in sufficient quantities should be used after the war (earlier, if possible) for the benefit of susceptible sections of the civil population.

There is the interesting question whether or not inoculation should be a general practice, comparable to that adopted and urged for children in the case of diphtheria. I should be interested to learn the views of your readers on this point.—I am, etc.,

Sturry. L. J. GREEN.

Identification of Gas Cylinders

SIR,—We have read with interest the note on the "Identification of Gas Cylinders" (March 17, p. 381), and particularly the concluding sentence that accidents due to misidentification of gas cylinders are not, unfortunately, rare, and that if the anaesthetists would agree upon standard markings doubtless manufacturers would at once meet their wishes.

Unfortunately the matter is not so simple as your contributor apparently believes, since the solution of the problem involves negotiation and agreement between several interested parties in this country and over-seas; it is not dependent on the anaesthetists alone.

Steps to deal with the situation that exists have been taken already by the Council of the Medical Defence Union and the Association of Anaesthetists acting in conjunction with national manufacturers of gaseous anaesthetics and anaesthetic apparatus. At a conference of these parties it proved practicable to secure the adoption of and the assurance of the immediate application of a "short-term policy" whereby the manufacturers undertook to carry out the following improvements related to the identification of gas cylinders:

1. The effective colouring of cylinders containing gaseous anaesthetics to enable the cylinders and their contained gases to be identified unmistakably by the colour employed.
2. The labelling or stencilling of the cylinders with the appropriate name of the contents or the chemical formula.

A "long-term policy" dealing with the undermentioned aspects of the problem was prepared and submitted to a special committee established under the aegis of the British Standards Institution. This committee consists of representatives of the professional, technical, and commercial interests involved and it has a reference calling for an examination and report upon suitable measures that may be adopted for the avoidance of accidents arising from errors of identification of gas cylinders and on other cognate matters relating to the use of coloured tubing, adapters, outlets, safety valves, etc. It is eventually hoped that a common measure of agreement will be secured with regard to standard specifications on these several items of equipment that are commonly employed by anaesthetists in their work.

The "long-term policy" envisages:

1. The incorporation of safety valves in cylinders containing gaseous anaesthetics.
2. The use in hospital and private practice of non-interchangeable couplings.
3. The use in hospital and private practice of an approved colour scheme for anaesthetic tubing.
4. The regular periodic servicing and inspection of anaesthetic apparatus in hospitals by approved manufacturers.
5. The use of fixed metal tubing in place of rubber tubing on integral machines.

Manufacturers are anxious to assist in every direction possible, but emphasize the impracticability of introducing extensive and costly changes in the midst of a war when labour problems are acute and material is in short supply. International standards and specifications will also call for consideration by the committee, and it is sincerely hoped that progress will be made to obviate the confusion arising from the interchanging and use of gas cylinders of foreign origin.—We are, etc.,

JAMES FENTON,
President, Medical Defence Union.
ARCHIBALD D. MARSTON,
President, Association of Anaesthetists.

SIR,—Every practising anaesthetist will applaud your medico-legal note (March 17, p. 381), since each of us is looking forward to the time when all cylinders are distinguished not only by colour but also by size of nozzle. I believe that the Association of Anaesthetists is at this moment actively engaged in obtaining this, and their efforts are receiving the sympathetic attention of manufacturers. Accidents are not heard of because most of them terminate favourably, but if Prof. Macintosh's suggestion were adopted that all anaesthetic deaths should be reported we should learn a lot about connecting up cylinders wrongly.—I am, etc.,

London, W.1. R. ERSKINE-GRAY.

SIR,—It is to be hoped that anaesthetists and hospital authorities will give careful attention to the medico-legal problem involved under the heading "Identification of Gas Cylinders" (March 17, p. 381).

With this problem in view the anaesthetic apparatus in the new operating theatre at the South Middlesex Emergency and Fever Hospital was specially designed. Here we do not rely on any colour system (as your contemporary recommended), but employ such devices as non-interchangeable yokes and couplings, so that a tragedy such as you describe is rendered impossible. By means of an automatic alarm system employing apparatus of a type used for many years in industry, and not "Heath Robinson" devices, another prevalent cause of anaesthetic deaths—namely, unobserved failure of oxygen supply—is eliminated.

All safety devices cost money, but where human lives are at stake this is of secondary importance. Pious recommendations are of no avail, but these deaths *could* be prevented by a suitable Act of Parliament compelling manufacturers and hospital authorities to adopt certain standards of safety in design, testing, and installation.—I am, etc.,

Twickenham. NORMAN R. JAMES.

Barotrauma

SIR,—Dr. A. B. Alexander (Feb. 24, p. 276) has suggested that the aural lesion produced in certain circumstances by changes of atmospheric pressure should be described as a "tubo-tympanic pressure syndrome" on the grounds of greater accuracy. With diffidence the following reply is submitted to his criticism of "otitic barotrauma," the term used by the Royal Air Force for the last three years. The former term is more general and therefore less accurate; it could be stretched to cover the case of the aviator who has "got away with" flying with a cold and has managed to maintain sufficient ventilation through his Eustachian tubes during descent to avoid damage to his drums, although experiencing symptoms. Such a patient would not be considered to be suffering from "otitic barotrauma," but would still be classifiable under the all-embracing "tubo-tympanic pressure syndrome."

Your correspondent objects to "otitis." If we accept the definition of inflammation as the response of injured but living tissue to the initiating trauma, then there can be no objection on terminological grounds. Clinically as well the classical features of inflammation are present—viz., *dolor, tumor, rubor, atque functio laesa.* Admittedly the *calor* component is more difficult of proof, but hyperaemia is an early sign and so *calor localis* would be there for any diligent seeker.

There can be little quibbling about "barotrauma," which is a gem of a word in both derivation and description. "Barotraumatic otitis" is therefore just as accurate a term as "traumatic synovitis" and better perhaps than "industrial dermatitis." Custom has led to the use of pure Latin for describing diseases of the ear, and so by analogy the condition should be "otitis barotraumatica." Some indulgence is here requested for the well-known word-coining propensities of the members of the R.A.F., who with their American friends are intolerant of redundancy, and so the anglicized "otitic barotrauma" has been produced with the doubtful disadvantage of interchange of noun and adjective but with an economy in a couple of syllables. Terminological purists can best settle with their consciences by using the abbreviation "O.B.," which, like "C.S.O.M.," has the great merit of brevity so woefully lacking in "tubo-tympanic pressure syndrome."

In conclusion I would like to thank Wing Cmdr. J. E. G. McGibbon for drawing attention to the benefits derived from auto-inflation with the head tilted slightly backwards (*B.M.J.*, Feb. 10) in correction of my statement in an article of earlier date.—I am, etc.,

R. M. S. MATTHEWS.

Another View on the Bassini Operation

SIR,—Like Elihu, the son of Barachel the Buzite, of the kindred of Ram, my wrath has been kindled and I am constrained to speak. For years it has been the fashion to malign the Bassini type of operation for inguinal hernia. I speak from memory, but so far as I recollect, during a discussion on inguinal hernia some years ago, Prof. Grey Turner was the only one who had a kind word to say in favour of this operation. As far back as 1927, when the Association of Surgeons met in Glasgow under the presidency of the late Prof. Archibald Young, I gave figures concerning 80 cases of inguinal hernia treated in Prof. Young's wards. Most of these had undergone an operation of the Bassini type. Prof. Young assessed the results. Of these 80 cases 4 were direct hernias and 76 indirect, 9 of which were of the "sliding" variety. There were 3 recurrences in the series. Eleven others were not reckoned complete "cures" because of neuralgia in the scar. Since then I have never failed to divide the inguinal branch of the ilio-inguinal nerve, and there has never been any complaint because of this.

Lately my junior colleague, Mr. Thomas L. Gordon, has investigated the cases of inguinal hernia treated by the Bassini type of operation in my wards in the Western Infirmary, Glasgow. He has included strangulated hernias in this series, and even then there is only a 3% recurrence rate. Mr. Gordon hopes to publish the details soon. There is no machinery at present that can determine a true recurrence rate. It would require a national register, and we should have to wait until every member of a large series of cases had died before we learned the *absolute* truth. Nevertheless, our investigation has been conducted as accurately as possible under war conditions.

I find it difficult to understand why such apparently uniformly bad results have been obtained by those who write disparagingly of the Bassini type of operation. I believe the worst results will be obtained by the surgeon who limits himself to one method of "curing" hernia; there is no one method suitable for every case. Allowing for this, a large proportion of inguinal hernias can be treated by the Bassini type of operation, and the results compare very favourably with those of any method. The following is a brief description of the operation I favour.

An ample skin incision is made so that no traction is exerted on the wound edges. The aponeurosis of the external oblique is split from a point lateral to the internal ring to the external ring. The upper leaf is then stripped from the underlying internal oblique and rectus sheath for at least three or four inches. This generally allows easy approximation of the conjoint tendon and the related muscles to Poupart's ligament with little or no tension. The lower leaf is similarly cleared to define the deep aspect of Poupart's ligament. The inguinal branch of the ilio-inguinal nerve is now removed. The cord is then lifted from its bed and the sac exposed and freed far up, much higher than the neck. At this high level it is cut away and the opening in the peritoneum closed by a continuous suture. The cremaster muscle and excess veins are removed. The canal is then repaired by approximating the conjoint tendon, etc., to Poupart's ligament, behind the cord, with four or five interrupted sutures of catgut not thicker than No. 1. Great care is taken to place these stitches at different levels so as to avoid splitting of the fibres of the ligament. A continuous suture of 4 or 6 "0" catgut is then applied over this to ensure that no underlying fat or other tissue can possibly be thrust through between the interrupted stitches should the patient be sick during recovery. The cord is then placed on the new floor and the external oblique aponeurosis stitched. The deep fascia is always sutured as a separate entity and the skin wound closed. Careful haemostasis is necessary throughout. An ample dressing is applied and retained in position by a firm spica bandage. The patient is nursed on his back and the knees are not flexed; this ensures that general healing and the adherence of the various layers of the abdominal wall take place in the fully extended position. If the patient's hips are flexed, either by the use of a knee pillow or by raising the head and shoulders, healing occurs in this flexed position and a very pronounced strain is put on the repair when the patient is allowed up and tries to assume the erect posture. The patient is kept three weeks in bed, but is allowed to move freely after the first week so long as he returns to the fully extended position.

In the prevention of recurrence I consider that free exposure is important and, even more so, absence of haste: never look at the clock; do the job carefully and well no matter how long it takes. Most important of all is delicate handling of the tissues. There is a class of elderly patient with very degenerate tissues in whom almost any operation is doomed to failure. I am presuming that those cases are only dealt with should an emergency arise, such as strangulation. Recurrence in such cases is almost unavoidable.

The last paper dealing with inguinal hernia appeared in the *British Medical Journal* of March 3 (p. 296) by Mr. Percival P. Cole. He, like so many, finds that most recurrences occur after the Bassini operation or one of its modifications. As stated above, this is not my experience. He goes back to the silver filigree. I made many filigrees for the late Sir Kennedy Dalziel when I assisted him away back in 1911. As time went on he gave up the method, and personally I have not tried it since. In the rare cases that require extra support fascial strips are used from the external oblique aponeurosis, leaving them attached at the pubic end.

I was amazed to learn in the memorandum issued by the Army Medical Department that "sepsis" is "relatively common." As a junior I was brought up to believe that sepsis, occurring in a clean operation of choice, was entirely the fault of the surgeon, and I was told in no measured terms that if I could not perform a clean operation without incurring sepsis I should give up surgery. I was allowed no excuses. In no case of inguinal hernia treated in my unit has there been sepsis. Why should sepsis occur in an operation of choice? The causes are much the same as lead to recurrence—i.e., small incision, because excessive traction is used to gain exposure, rough handling, and haste. Mr. Cole had no case of sepsis in his series, and that is as it should be. But he attributes this to non-touch technique. Now I think non-touch technique a snare and a delusion. If a surgeon cannot trust his hands as much as his instruments something serious is wrong.

Recurrences were met with all too frequently in the first three or four years of this war. Among such I dealt with two cases repaired elsewhere by fascial suture and one by floss silk (this had become septic in the presence of a carbuncle). In several others it was impossible to determine what method had been used; in some the sac only appears to have been removed. It so happens that none was of the Bassini type. I have a shrewd suspicion that there would not have been such a flood of recurrences if junior surgeons had been taught to do a simple operation such as I have described rather than embark upon more intricate procedures.

I started with a quotation from the Book of Job; let me finish with one from Shakespeare: when there is a recurrence "the fault, dear Brutus [or surgeon] is not in our stars [or choice of operation] but in ourselves."—I am, etc.,

ANDREW J. HUTTON,
Visiting Surgeon, Western Infirmary, Glasgow.

Prophylaxis of Trench Foot

SIR,—I had not intended to reply to Dr. A. W. Forrest's letter (March 10, p. 344), which expresses so complete an ignorance of the subject of trench foot that it seems to answer itself. I am, however, induced to change my mind by some who feel that public policy demands it. I shall not, however, follow his example of wasting much of your valuable space.

There was nothing "novel" in my paper. It was a summary of the methods of prophylaxis which were found highly effective in the last war, and which, by their strict application in this war, have reduced the British casualties from this cause to negligible numbers in circumstances of the greatest hazard.

I think that Dr. Forrest may assume that my "strong words" do, in fact, meet with the approval of the fighting Services. I have had ample assurance of this from the highest quarters. To the best of my knowledge neither the University of London nor the British Postgraduate Medical School has formulated an official policy on the prevention of trench foot. We have not yet reached a stage of Fascism in which such bodies censor the views of lecturers within their walls.—I am, etc.,

Whitchurch, Bucks. RAYMOND GREENE.

Ovariotomy or Caesarean Section?

SIR,—I deprecate any hard-and-fast rule as to whether ovariotomy performed on a patient with a viable pregnancy should or should not be accompanied by Caesarean section. Surely it depends on how far the patient is from term. If the time is considerable natural delivery should be awaited, but if labour is shortly due the question has to be considered whether it is desirable to let the patient undergo a second operation, albeit she carries out that operation on herself. I think the patient and her husband should decide this after the pros and cons have been explained to them.

When the ovariotomy has to be undertaken because the labour is obstructed, whether the child should be delivered by Caesarean section or not largely depends on the state in which the obstructed labour has left the patient. If this is unsatisfactory Caesarean delivery is unquestionably indicated. I can imagine the despair of a woman who, having already suffered for many hours, awakes from the anaesthetic to find she still has to undergo the pangs of labour, made worse by the pain of an abdominal wound. If men, instead of women, bore children I fancy that the teaching of certain professional obstetricians would undergo some modification.

Mr. Stanley Way's letter (March 17, p. 384) interests me, and I entirely agree that, when an ovarian cyst in a relatively young woman is operated on, the cyst should be enucleated and not dealt with by ovariotomy. I have strongly advocated the enucleation of ovarian cysts ever since I accidentally discovered, in 1916, that they could be enucleated; and I have ventured to coin the name of "ovarian cystectomy" to distinguish this operation from ovariotomy, in which the ovary is removed as well as the cyst. If Mr. Way will look up the literature he will find that in 1924 I stated that all innocent ovarian cysts and many innocent solid growths of the ovary could be enucleated, and I have written on the subject many times since. I am, however, glad to read Mr. Way's confirmation. I have now performed the operation just over 300 times without a death, and have several times enucleated cysts weighing over 20 lb.—I am, etc.,

London, W.1. VICTOR BONNEY.

Flour in the Loaf

SIR,—In the *Journal* of March 17 (p. 393), in a report of the House of Lords debate on Feb. 28, you cite some remarks by the Earl of Portsmouth about Bemax, a product of my company. I realize that in the course of a summary of the proceedings in the House of Lords it is entirely natural that you should include Lord Portsmouth's remarks, but it is unfortunate from my company's point of view that Parliamentary privilege prevents my dealing with their inaccuracies as effectively as would have been possible had they been made outside the House. I feel therefore bound to ask for the hospitality of your columns to refute Lord Portsmouth's statements.

I will confine my comments to those points which are likely to be, if uncontradicted, most damaging to my company's reputation. He stated that Bemax "was largely the result of removing the most valuable constituents from the wheat berry before it was made into white bread." This statement bears no relation to fact. Not a single particle of Bemax is derived from wheat or flour intended or actually used for the manufacture of bread. For the benefit of your readers who are not familiar with milling processes and the current law on the matter I ought to explain that the removal of germ from flour intended for bread-making is strictly prohibited by current regulations (S.R.&O., No. 11, 1943), and to my personal knowledge and to the knowledge of everyone who has any connexion, direct or indirect, with the milling industry, these regulations are rigidly enforced. The facts just cited have been publicly mentioned in both the House of Commons and the House of Lords (see, for example, Hansard, June 9, 1942, June 30, 1942, July 16, 1942, July 21, 1942, Aug. 14, 1942, July 23, 1943, etc.). It is clear, therefore, that Lord Portsmouth failed to study in advance the subject on which he was to speak.

The raw material from which Bemax is prepared is extracted solely from flour destined for manufacturing purposes—purposes in which the vitamin B_1 will in any case be unavoidably destroyed in whole or in major part by the subsequent manufacturing processes. Its extraction for use as Bemax represents, therefore, a far-sighted and wise "salvage" policy in relation to nutritional needs and not, as is clearly implied by Lord Portsmouth's remarks, a worsening of general nutrition via bread for the benefit of private interests. Lord Portsmouth further alleged that Bemax supplies the most valuable constituents of the wheat berry at something like a hundred times the price they would cost if they had been left in the loaf. These fantastic allegations as to the relative cost of Bemax and bread are, in any case, irrelevant, because Bemax is not "subtracted" from the loaf; but even if this were not so, the extent to which Lord Portsmouth's statements deviate from a fair comparison may be gauged from the fact that the cost of vitamin B_1 in Bemax is slightly less than its cost in the loaf, notwithstanding the subsidy on bread. A similar comparison in respect of other factors of the B complex, as well as of other nutrients, is equally favourable to Bemax. If indeed the product had ever been sold at an exorbitant price, normal competition would long ago have operated to reduce it.

For many years my company and its scientific staff have contributed to the advance of nutritional knowledge. Our educational publications have always stressed the nutritional advantages of wheatmeal bread. Some of these publications are widely used in the schools and have been incorporated by independent authors in medical and nursing textbooks. If, therefore, we are again to be attacked publicly in this manner I trust that it may be in circumstances of a nature which can be dealt with by ordinary legal processes.—I am, etc.,

H. C. H. GRAVES,

Hammersmith, W.6. Chairman and Managing Director, Vitamins Ltd.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The Council of the Senate and the General Board have issued reports on the establishment of a Professorship and a Department of Experimental Medicine (*Cambridge University Reporter*, March 14, 1945). In 1931 the Council had under consideration the setting up of a professorship of experimental and clinical medicine, recommended by its committee which considered the position of medical studies in the University after the death of the Downing Professor of Medicine. The Council could not then accept its committee's recommendation, because the chair could not be established without a large benefaction. In its statement on post-war needs a year ago the Faculty Board of Medicine recommended the early establishment of a department and professorship, and said it would welcome the appointment of Dr. R. A. McCance as professor if it were found possible to establish the department. In its report dated Feb. 28, 1945, the General Board makes known an offer by the Medical Research Council to provide the stipend of Dr. McCance as professor, and also to increase substantially the financial support which it is already affording to Dr. McCance's researches. The Council of the Senate is of opinion that advantage should be taken at once of the generosity of the M.R.C., for this now makes it possible to bring into being a professorship it has long wished to establish. In order, however, that the University may be free in its plans for the future the Council proposes that the professorship be limited to one tenure. Other recommendations are that the professor shall not engage in private practice, and that the chair be primarily assigned to the Faculty of Medicine and come into being on Oct. 1 next. Dr. McCance's present position is that of Reader in Medicine.

E. Cronin has been approved for the degree of M.D. in absence.

UNIVERSITY OF SHEFFIELD

Dr. H. A. Krebs has been appointed to the newly created Chair of Biochemistry. Prof. Krebs first went to Sheffield from a post at Cambridge nine years ago and, as lecturer, founded there a school of biochemical research which his work has made very well known in scientific and medical quarters of the world, attracting researchers from other places, including the United States, to work under him, and winning substantial support from such bodies as the Medical Research Council and the Rockefeller Foundation of New York. He has taken an active share in organizing and conducting a number of nutritional studies for the Government during the war.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At an ordinary meeting of the Council held on March 8, with Sir Alfred Webb-Johnson, President, in the chair, it was reported that Sir Hugh Devine was admitted to the Honorary Fellowship of the College in Melbourne on Feb. 24 by H.R.H. the Duke of Gloucester.

It was decided to continue recognition of the Walton Hospital, Liverpool, under the F.R.C.S. regulations in respect of the posts of resident surgical officer, second resident surgical officer, and senior house-surgeon. It was also decided to amend the regulations for the Fellowship examinations so as to extend admissibility to the examinations to holders of any medical qualification registrable on the British *Medical Register*.

Sir Arthur MacNalty was appointed Thomas Vicary Lecturer, and Prof. W. E. Gye, F.R.S., and Dr. L. Foulds Imperial Cancer Research Fund lecturers in the College for 1945.

Diplomas of Membership were granted to J. A. Litchfield and R. E. Moore.

Diplomas in Ophthalmic Medicine and Surgery and in Medical Radiology were granted jointly with the Royal College of Physicians of London to the following successful candidates:

DIPLOMA IN OPHTHALMIC MEDICINE AND SURGERY.—P. L. Allen, J. Berkson, E. A. Butterworth, J. S. Crawford, G. P. Crookes, A. Dala, W. M. C. Gilmour, H. L. Gulati, J. R. C. Holmes, G. A. D. Lamb, R. L. Parish, J. M. Posada, S. P. Redmond, Jane P. Smith.

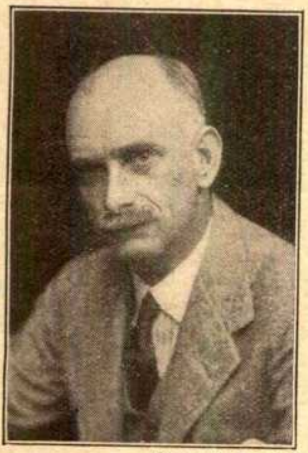
DIPLOMA IN MEDICAL RADIOLOGY.—M. Bennett, V. J. Coffey, J. C. Dore, E. W. Hyde, Katie H. Jones, K. M. N. McMahon, B. Mannheimer, S. L. Mitra, A. D. O'Connor, D. P. O'Sullivan, T. R. Riley, K. Sicher, W. G. Smith, R. E. Steiner.

Obituary

SIR THOMAS LEWIS, C.B.E., M.D., F.R.S., LL.D., D.Sc., F.R.C.P.

Sir Thomas Lewis, physician to University College Hospital, and Director of the Department of Clinical Research and Holme Lecturer in the medical school, died at Rickmansworth on March 17. For many years he had been engaged solely in teaching and research.

Born in 1881 son of Henry Lewis, J.P., of Tynant, Taff's Well, near Cardiff, he was educated at Clifton College, at University College, Cardiff, and at U.C.H. He gained first-class honours in the Final B.Sc. at London University, qualified in 1904, and graduated M.B., B.S.Lond. with the University Medal, and D.Sc. of the University of Wales. He won clinical and pathological medals at U.C.H., was elected assistant physician not long after taking his M.D., and became F.R.C.P. in 1913. He was also for a time physician to the City of London Hospital for Diseases of the Heart and Lungs, Victoria Park. In 1908 he asked A. S. MacNalty to work with him on heart-block. This was the first investigation on a human subject in which the electrocardiograph was used, and a joint paper entitled "A Note on the Simultaneous Occurrence of Sinus and Ventricular Rhythm in Man" appeared in the *Journal of Physiology* that year. For his contributions to cardiovascular physiology, on which he gave the Croonian Lecture to the Royal Society in 1917. Thomas Lewis was elected F.R.S. in 1918, and in 1927 was awarded a Royal Medal. Much of his work which formed the basis of his Croonian Lectures before the Royal College of Physicians in 1926 had been published in detailed form in a series of original memoirs printed chiefly in *Heart* and in the *Journal of Physiology* from 1916 onwards. This wealth of experimental material during eleven years appeared as a monograph, *The Blood Vessels of the Human Skin and their Responses* (1927); by that time all the world of medical science knew of the leading part played by Thomas Lewis in that remarkable advance in clinical knowledge of the defects of the heart's action, made possible by experimental analysis of the mechanism of the mammalian heart beat.



[Photo by Vandyk

During the last war he served as consulting physician on diseases of the heart to the Eastern Command, and for this was awarded the C.B.E. in 1920; he was knighted a year later. After the war he acted as honorary consulting physician to the Ministry of Pensions. He received honorary degrees from the University of Wales (when he was President of the Section of Medicine at the B.M.A. Meeting at Cardiff), and from the Universities of Sheffield, Liverpool, Birmingham, and Michigan. He was a Foreign Member or Honorary Fellow of more than a score of universities and academic institutions abroad, and was awarded the Mitchell Prize by Toronto in 1933. He received the Copley Medal—the highest honour of the Royal Society—in 1941, and in 1944 the Presidents of the Royal Society and of the Royal College of Physicians awarded him the Conway Evans Prize for his great contribution to medical knowledge on the normal and abnormal mechanisms of the heart and circulation of the blood. His Harveian Oration to the R.C.P. twelve years ago was entitled "Clinical Science," and that was the name of the journal which he founded and edited in succession to *Heart*. Of Lewis's important writings published in book form *The Soldier's Heart and the Effort Syndrome* reached a second edition; *Mechanism and Graphic Registration of the Heart Beat*, a third; *Clinical Electrocardiography*, a sixth; and *Clinical Disorders of the Heart Beat*, a seventh. The results of his researches were brought before the general medical public in several masterly articles written by him for this *Journal*.

Sir Henry Dale, O.M., President of the Royal Society, sends the following appreciation:

With the death of Sir Thomas Lewis, at an age when his mental vigour had suffered no decline, we have lost an experimental scientist and physician of the highest rank. As is well known, Lewis very early made it his life's aim to establish in this country a strong and progressive tradition of direct experimental research on disease in the human subject, and to the furtherance of that aim he devoted the whole strength of his indomitable and uncompromising character, as well as his rare abilities.

The son of a distinguished mining engineer, a man of great influence in the South Wales coal industry, Lewis had an unusual education. But for a brief period at Clifton he was tutored at his parents' home, where, apart from formal learning, he acquired his abiding love of the country and trained his remarkable powers as an observer of Nature, which were to become so important a part of his equipment as physician and man of science. He decided to be a doctor before he entered his teens. The precocity of the decision was characteristic, as was, perhaps, the reason for it: two doctors who attended his family both happened to be conjurers, and young Tom supposed that a medical training would be necessary to enable him to rival their dexterity. Certainly a remarkable manual skill was to play its part, together with a persistent curiosity about natural phenomena and a rare alertness and accuracy of observation, in making the brilliant research worker which the boy was to become. Until he was 16 it does not seem to have occurred to the young Lewis that there was any need for him to work at his studies. They would, in any case, have come easily to him, and there were so many things in his country life to attract and hold his interest more readily; but to suppose that in any moment of his waking life his brain was ever idle, relaxed, or inattentive is just impossible to anybody who knew him in after-life. He reached a turning-point when at the age of 16 he sat for the London Matriculation Examination, and failed. That was, of course, enough for Lewis; he forthwith applied himself to his books, and thereafter he never failed in an examination. At Cardiff he worked hard, and by the time he was 20 he was demonstrating for the professors of anatomy and physiology. Swale Vincent, professor of physiology, helped him to his first experience of research. In 1902, at the age of 21, with an entrance exhibition, he entered University College Hospital, London, with which his connexion was to continue to the end of his life. All through his student career he was giving spare time to odds and ends of research, and meanwhile, in the informal friendliness of encounter at teashop luncheons, he was learning from seniors of the calibre of Horsley, Bayliss, and Starling, all quick to recognize the quality of this young man from Wales. He was lodging, too, at this time and making a lifelong friendship with T. R. Elliott, by some years his senior. Lewis, indeed, had a precocious maturity of outlook and scientific judgment which made it natural for him to associate with older men; though he was my own junior by 6½ years, it never occurred to me to think of him as other than a contemporary in scientific development and experience. I remember the impression of assured scientific competence and judgment produced by his first serious piece of research, on sphygmograph records, when he described it to the Physiological Society. Lewis continued this work on pulse records in Starling's laboratory until he met James Mackenzie, whose stimulating influence turned his attention to the analysis, by the experimental methods then becoming available, of the ventricular irregularity which Mackenzie had called "nodal rhythm." Another influence at that time must have been the arrival at University College of Cushny, who had already produced auricular fibrillation experimentally. These contacts, together with Einthoven's introduction of the string galvanometer, set the stage for the research which was to establish Lewis's reputation as a medical investigator of achieved distinction and of tremendous promise.

Meanwhile he had been dividing his time between research, the tenure of appointments at minor hospitals, and occasional private consultations. His foot was, in fact, already well on a ladder leading to success as a consulting physician; but this was not the career on which he had set his heart. He had tasted the joys of research and had begun to be conscious of his life's mission, and to mistrust the possibility of dividing his time and attention between a concentrated investigation of one chosen problem and the finding of rapid solutions for a mixed succession presented from outside. In 1910 the first appointment of Beit Memorial Research Fellows gave Lewis a further chance; he was an applicant, and his name stands first on the now long and distinguished list of those who have been Beit Fellows. His tenure was brief, however, for in 1911 his old hospital gave him a lectureship, made him an assistant physician in 1912, and a consulting physician in 1913. He was now immersed in his great series of experimental researches on the mechanism of the heart beat, and this work was earning him recognition in the U.S.A. at least as soon as in his own country; for in 1914, still at the remarkably early age of 33, we find him delivering the Herter Lectures at Baltimore, a Harvey Lecture in New York, and remaining for a spell as a visiting physician attached to the Peter Bent Brigham Hospital at Boston. His experimental work of this period, published in a masterly series of papers in the *Philosophical Transactions of the Royal Society*, and summarized in 1917 in his Croonian Lecture, must certainly rank as one of the outstanding achievements of physiology in our own or, indeed, in any time. For Lewis, however, it was merely the necessary background for a planned lifetime's study of the disturbances of the normal mechanism by disease.

In 1916 Lewis's career and opportunity were finally settled by his appointment as the first whole-time research physician on the staff of the Medical Research Council, with a ward and laboratories placed at his disposal by University College Hospital. Years later, in 1937, the support of his appointment there, as chief of a department of clinical research, was transferred to a special Trust endowed by the Rockefeller Foundation; but Lewis's research colleagues remained on the staff of the Medical Research Council. In its first few years the new department's activities were much scattered and interrupted by Lewis's service as consulting physician to military hospitals. But out of these war years came his well-known studies of the "effort syndrome" ("soldier's heart"), and the first stage, published with Cotton and Slade, of his second major series of researches, dealing with the reactions of the peripheral blood vessels, and eventually embodied in his remarkable monograph (1927), packed with original observations, on *The Blood Vessels of the Human Skin and their Responses*—a very model of what can be done by direct experiment on the human subject, with a minimum of apparatus, but with a naturalist's faculty of observation sharpened to the finest edge of precision. Here again Lewis's aim had been to get for himself an exact picture of normal reactions as a starting-point for his study of their modification by disease or by inborn abnormality.

Time and space alike forbid a detailed account here of the achievements in clinical research of Lewis and the school which he founded. As years went on the centre of his thoughts and his interest was more and more occupied by the importance of his mission—of his duty to the future of medicine, especially in his own country, and of proclaiming its needs at every opportunity. The sword must not sleep in his hand till he had built here a temple for the service of medicine by the direct experimental investigation of disease in man, with proper careers and prospects open to its priesthood and its votaries. Some might urge, not without some justice I think, that the aspects of human disease open to investigation of this kind were its results—the symptoms which Lewis and his colleagues analysed into their physiological components with such beautiful precision—and that the whole range of aetiology, whether infective, nutritional, or genetic, must be almost entirely outside its scope. The main thing was that Lewis was creating an atmosphere in which medical research in the clinic was regarded as an absorbing aim and ambition, and not as a spare-time incident in a career leading to consulting practice; that the young men rallied to his banner; that they learned his great language, caught his clear accent, and lived in the gleam of an eye—the eye of an eagle—which was always magnificent, indeed, but mild only on occasions when the mission was momentarily out of his mind. They, and we all, have lost a great leader; but his spirit goes marching on.

Till 1927, when serious illness struck him where he most clearly knew its meaning, Lewis had worked for ten months of every year with a concentrated energy which left his junior colleagues panting with the effort to keep pace with him. In the other two months, taken always as a continuous vacation, he put medicine completely out of his mind but gave himself with a like enthusiasm, and with all that training and perfection of equipment could provide, to watching and photographing the birds which he so loved. After his first illness he put this joy, with its temptations to physical strain, out of his thoughts; he moved into the country, gave himself more regular leisure to enjoy his garden, and chose the quieter distraction of fishing for his holidays. He knew what was before him. "Another arrow from the same quiver, my friend," he said to me when a second, less severe attack came in 1935; "but there are plenty more to come, and one of them will get me in the end." Meanwhile, with a magnificent courage, he succeeded in what, for him, must have been the most difficult of all achievements—schooling himself to work at a reasonable pace. To this he was helped beyond measure by the serene happiness of his marriage and his family life, in which the affection which was at the real, warm heart of him overflowed in joy and pride. To his widow, his son, and his two daughters, and to those of us who knew him as one of the most loyal and generous, if not always the easiest, of friends, there must remain, in the midst of sorrow, the thought that he has gone before age could weaken the spring and eagerness of his wonderful mind and spirit.

In his approach to medical research, as in the quality of his genius, I believe that Thomas Lewis was the nearest successor which our generation will see to his own great pattern and exemplar, William Harvey.

Prof. T. R. ELLIOTT, F.R.S., writes:

We have lost a great leader in medical science, taken away untimely when his powers were still at their highest, but not before he had seen happy proof that an aim for which he had striven with intense ardour was now being widely understood and that more than his discoveries would live on as the outcome of his work.

Sir Thomas Lewis received the highest honour our country can give for original discovery in pure science—the Copley Medal of the Royal Society in 1941. Very rarely has an active clinician gained this distinction, though the medal is given yearly. The last before Lewis was 40 years earlier—Lord Lister. That gives a measure of his achievements in fundamental science. In medicine he changed the approach of every practitioner to the analysis of heart disease with such completeness that now we use his teaching so naturally that few recall its origin in Lewis's work. First came his handbook on *Clinical Disorders of the Heart Beat*, 1912. Earlier than that, though only in his thirtieth year, he had published a classical monograph on the *Mechanism of the Heart Beat*, based on his own studies with Einthoven's galvanometer; but that was for advanced workers in the subject, as was also the journal *Heart* which, with Mackenzie's help, he founded at the same time. So he proceeded to an exact clinical study of the natural progress during life of each type of derangement of the beat, defined simple clinical means for recognizing the types, and then in his handbook set out the results with an admirable clearness that enabled all to make use of the new knowledge. Twenty years of patient study of all forms of heart disease followed, every detail being recorded and analysed with scientific accuracy, and nothing left to an easy generalization from uncertain memory or intuitive opinion. Added to this was the experience that routine teaching to medical students gave him in shaping his views to easy comprehension at the bedside. Then he wrote his second book for direct clinical use, *Diseases of the Heart*, 1932, emphasizing in it the simple principles for estimating what a murmur could never tell—the functional efficiency of the heart at each stage of disease. That now belongs to common knowledge.

Lewis thought it his duty to write these books for use in medical practice. But the discovery of new knowledge was his burning desire, and he grudged bestowing time on any other end. Coming to London at an era when endowments for research were beginning to make it possible for a man to think of such a life in medicine, he found that hope progressively fulfilled and was soon able to free himself from any fettering interests of consulting practice. So, when the field of work in electrocardiography seemed exhausted, he could easily abandon both it and his reputation as a heart specialist and move to new work on skin capillaries. Here he now used the simplest forms of experiment and apparatus, but with them his penetrating genius carried him to fundamental discoveries of vascular reactions to nervous stimuli or to chemical substances produced by injury of tissues. The problem of pain, especially that arising from deep tissues, was also prominent in his later work.

Throughout the second half of his life he was driven by a bigger and wider aim than that of his own individual discoveries. Physiology, through his contact with Swale Vincent at Cardiff and later with the great leaders at University College, had first sway with him, and indeed it dominated all his researches so that much of his work might be described as a physiological analysis of clinical symptoms. But Lewis was intensely conscious that what he desired was more than a co-operation of physiology with medicine. He knew there were innumerable problems in medicine for the solution of which little sustained work was being attempted, and he wished to see clinicians themselves using every science, not only physiology, for an exact study of the problems which they alone were by their experience enabled to define. The words in 1869 of Sir James Paget, himself a physiologist and pathologist as well as surgeon, gave both the phrase and the thoughts that were later advocated with such intensity by Lewis. "I feel sure that clinical science has as good a claim to the name and rights and self-subsistence of a science as any other department of biology. . . . Receiving thankfully all the help that physiology or chemistry or any other sciences more advanced than our own can give us, and pursuing all our studies with the precision and circumspection that we may best learn from them, let us still hold that, within our range of study, that alone is true which is *proved clinically*, and that which is clinically proved needs no other evidence."

Lewis had by his own thought reached the same view, and he pursued it with the devotion of a zealot. A strong sense of realities made him aware that he must inspire a band of workers, and find for them opportunities for research similar to his own, if the subject of clinical science were to attain the permanent strength that he believed to be essential for the advance of medical skill. For this end he founded a Medical Research Society, and changed the title of his journal *Heart* to that of *Clinical Science* so that it might become the journal of the new society. All was prospering hopefully. Then came the scattering outburst of war, and Lewis himself will not see the recovery. But he has left behind him men who will assuredly maintain the movement.

Lewis was very loyal to University College Hospital by reason of its scientific traditions and could never be persuaded to leave his school. For more than twenty years he was the mainstay of scientific work there, picking out and inspiring younger men, conversing with all and upholding the highest accuracy of thought. He devoted endless care even to elementary teaching, and his lectures were models of clearness both in thought and voice. All his energies were focused on such work, and from older men he resented opposition or lukewarmness where he looked for strong support But that was an affair of the moment, soon forgotten when one thought of the nobility of his aims and the excellence of his work. Of personal conceit he had none, and his eagerness to help and teach them made every student at the school speak of him simply and affectionately as Tom Lewis.

E. M. EATON, M.D., D.O.OXON, F.R.F.P.S.GLAS.

We announce with regret the death of Mr. Ernest Milne Eaton at Lanark, Scotland, on Feb. 3 at the age of 61, after an illness lasting about two years. He had been in practice in the Blackpool and Fylde district as an ear, nose, and throat specialist since 1928, and was consulting aural surgeon to the Victoria Hospital, Blackpool, to Fleetwood, St. Annes, and Lytham Hospitals, and to the Corporation of Blackpool. After graduating M.B., Ch.B. at Glasgow in 1906, he was house-surgeon to Sir William Macewen and assistant to Prof. Cleland in the anatomy department of the University. In 1910 he went to Australia, where he practised as an eye specialist in Queensland. On the outbreak of war in 1914 he came with the Australian Red Cross to France (No. 2 General Hospital, Rouen); he later joined the R.A.M.C., and saw service as eye specialist with the rank of captain on the Italian front. After the war he spent two years as assistant surgeon in the Ear, Nose and Throat Hospital, Glasgow, with the late Dr. W. S. Sime, whose book he helped to edit and illustrate. Then followed four years in successful general practice at Maidenhead, Berks, after which he returned to oto-rhino-laryngology, holding appointments in London as surgeon to the Invalid and Crippled Children's Hospital, and surgical registrar at Golden Square Throat Hospital.

The more mature years of his professional life were spent in Blackpool, where he will long be remembered and honoured. Although a confirmed bachelor, it seemed fitting that he should enjoy an almost parental authority amongst the medical profession in Blackpool. He was by common consent the chairman of nearly all medical committees and meetings, and for three years served as chairman of the Medical Board of the Victoria Hospital, Blackpool. As a chairman he excelled in putting the main issues clearly and logically before a meeting, and none could equal him in the exact and accurate framing of a resolution. This facility with words will be perpetuated in the by-laws and regulations of the Victoria Hospital, Blackpool, which were largely his work. His powers of debate, based on wide knowledge and experience, were of a high order. During the period of reorganization before and after the rebuilding of the Victoria Hospital on its present site in 1936, he took a leading part in promoting conditions which have since made possible the development of a full consultant service based on this hospital. His later interest was in the regional development of hospital services, and he worked hard and successfully for the recognition of the North-West Region of the British Hospitals Association. His professional reputation was built upon the consistently high quality of his work, this being fully recognized by his colleagues, who entrusted themselves and their families to his care with complete confidence that the best would be done for them. Motor-boat racing and yachting at Windermere were his principal recreations, and in these also he displayed his accustomed skill and thoroughness. During the year 1935 he had the honour of being elected Commodore of the Windermere Motor-boat Club. He was a member of the British Medical Association for many years, and gave valued service to the local Executive Committee.

I. B. T.

G. L. TAYLOR, M.D., PH.D., F.R.C.P.

We announce with much regret the untimely death of Dr. George Lees Taylor. He was born in 1897, son of Albert Taylor, of Ashton-under-Lyne. After leaving the Manchester Grammar School he went to Manchester University, where he was a medical student of exceptional distinction. After qualifying he was house-surgeon to Sir William Thorburn and house-physician to Dr. G. R. Murray. Following a period as obstetric house-surgeon to St. Mary's Hospital, Manchester, Taylor went for a time into general practice. In 1929, however, he decided to devote himself to medical research and teaching, and for six years worked as John Lucas Walker Student under Prof. H. R. Dean in the Department of Pathology at Cambridge. In 1930 he took his M.D.Manc. and in 1932 the Ph.D. of Cambridge. In 1939 he was made a Member and in 1944 a Fellow of the Royal College of Physicians.

In 1935, through the generosity of the Rockefeller Foundation, a unit devoted particularly to the study of blood groups in relation to human genetics was established in London. Taylor was well qualified to take charge of this work, though few could have foreseen then how brilliantly he would be able in the next few years to develop the subject. It was most fortunate that he was able to see this new enterprise through from 1935 to 1939 in the Galton Laboratory at University College, London, and from the outbreak of war under the Medical Research Council at Cambridge. At Cambridge the unit undertook work of national importance for the Blood Transfusion Service.

Taylor's published work, which includes 41 papers of which he was author or part author, falls into two groups. In the work described in the first group of 10 papers, dealing chiefly with the precipitin reaction, he was collaborating closely with Dean and the two Adairs. These papers well illustrate Taylor's immense thoroughness and pertinacity. In 1935 serological genetics had been rather neglected in this country. Not much had been done even on the spontaneous agglutinins of the OAB series, and few had any real experience of the M and N factors. It was clear that extension of knowledge of this field must be made if there was to be any progress in mapping out the human germ-plasm. Taylor set out to obtain the utmost reliability in the application of known tests; to examine the distribution of blood groups in this country; and to lay a foundation for linkage studies by including blood group and other genetical data in pedigree collections of a number of rare anomalies such as acholuric jaundice and Huntington's chorea. This programme required that he should familiarize himself with the intricate methods of genetics and statistics. At the time R. A. Fisher was Galton Professor, and the department in which Taylor worked was in a good position to aid the development of these new interests.

The rhesus factor, with which Taylor's name will always be associated, was first reported in 1939. The matter was at first thought to be genetically simple, but soon found to be complex: the beginning of Rh work in England may be said to date from a letter in the *Journal* in which Taylor and Mollison appealed for specimens of blood from mothers of children suffering from erythroblastosis foetalis. Within a year Taylor had become known to hundreds of pathologists and practitioners in all parts of the United Kingdom, and took endless trouble to explain to doctors and patients the significance of this fascinating blood-group factor. Within twenty months the Cambridge unit had discovered seven allelomorphs of the rhesus factor, and four distinct antibodies out of a now probable six. Almost simultaneously Wiener discovered six of these allelomorphs and three of the antibodies, so independently confirming the work of Taylor and his colleagues. It is characteristic of Taylor's generosity to the work of others that he did not hesitate to adopt Wiener's notation for the allelomorphs known to both, though their existence had been separately demonstrated. No one who has worked with Taylor could fail to recognize his scrupulous attention to detail, and the extreme care he took not to use a single word that might be misleading. In leading articles and answers to "Any Questions?" in this *Journal* he gave willing and invaluable help in explaining to the medical profession the advances made in his own field of study. His helpfulness was unfailing, and his loss will be felt by a very wide circle of friends. To his widow and daughter our sympathy is extended.

JOHN HOWELL, C.B.E., F.R.C.S.

The death occurred at Cheltenham on March 4 of Mr. John Howell, leading surgeon in Gloucestershire, where he had practised for nearly half a century. He went to Cheltenham as house-surgeon to the old Branch Dispensary, after qualifying at Guy's, where he held the positions of house-surgeon and obstetrical resident, and he was soon appointed to the honorary surgical staff of the Cheltenham General Hospital. This appointment was a happy one for all concerned, as he threw himself, with all his dynamic force and clinical acumen, into its service. Becoming senior surgeon in 1913, he remained on the active staff of the hospital until he attained the age of 60, retiring so that the younger generation might have greater scope for work. He might have remained on, but he felt it was his duty to retire, though at that time he was at about his best as a surgeon and consultant.

J. S. R. writes:

What the Cheltenham General Hospital owes to him cannot be easily evaluated; sufficient to say that, by his dynamic personality and foresight, he devised the plan of getting the various members of the surgical staff to make themselves proficient in special branches of their work and be responsible for cases coming in their specialty. In retrospect, this plan has been of definite value to the patients, doctors, and to the staff of the hospital. A regular feature for which Mr. Howell was largely responsible was clinical lectures and demonstrations by the members of the hospital staff each summer: these were very popular, and were looked on as a refresher course by practitioners in the county, being very well attended.

As a diagnostician John Howell was pre-eminent, and in abdominal surgery his "peritoneal theory," on which he was working up to a short time before his death, made him something out of the ordinary in regard to prognosis. How he loved to examine the various vomits, which had to be carefully kept, with the exact time at which they were expelled, and then say, "This patient will get better; this one is a borderline case; but this one, alas! will succumb." Succeeding house-surgeons used to marvel at his uncanny instinct. He wrote for a number of medical publications, but in his long and busy life he had not the time to work out his theories as he would have wished. As a surgeon he was quick, fearless, and always had a feeling that the body would co-operate loyally with the surgeon. He was always anxious to try anything new, but was nevertheless critical in his appreciation.

In the last war he was consulting surgeon to a group of military hospitals in this area, at which he gave invaluable service; his cheerful personality and buoyancy gave courage and hope in the most desperate cases, and the award of the C.B.E. for these services in 1919 was well merited and acclaimed. As a loyal member of the B.M.A. he acted as secretary of the Gloucestershire Branch for many years in his early days. He was a member of the Council, president of the Gloucestershire Branch in 1925, and vice-president 1930-5. At all times he took the most active interest in its proceedings, while in debate and discussions he was ever to the fore, as was to be expected of an ardent Welshman. As chairman of the Medical Services Subcommittee of the Gloucestershire County Council he did valuable work in the county, and was instrumental with the late Dr. Middleton Martin in introducing the scheme of "out-stations," whereby specialists made periodic visits to all parts of the county. This scheme has worked well, and is still functioning after more than 20 years, and proving of value, especially in the war years.

As a leading figure in the municipal life of Cheltenham for many years his ability and integrity were recognized when he was given the unique honour of being appointed mayor for three years. The Spa Committee of the town council found in him an ardent supporter, and a few days before his death he was interested in the arrangements for a meeting of the British Spa Federation in Cheltenham next month. As a crowning honour he was made a Freeman of Cheltenham a couple of years ago.

Space does not permit more than a brief mention of his many other activities: the Rotary Club, Chamber of Commerce, Child Guidance Clinic (much indebted to him for financial help at a difficult time), athletic clubs of which he was president. All these owed much to him. He seemed to say to himself, "Much has been done; much more remains to do." Music and art found in him an ardent supporter. At the funeral service heartfelt tributes were paid by a congregation which filled the parish church of Cheltenham. Six of his colleagues, representatives of the hospital and practitioners of the town and county, acted as bearers, paying in this way some small token of affection to one who had done so much for them. He leaves three sons (one of whom is Major John Howell, R.A.M.C., at present serving in Italy) and one daughter, to whom our deepest sympathy is extended.

GEOFFREY W. CARTE, M.B., F.R.C.S.

We regret to announce that Mr. Geoffrey Williams Carte, late surgeon to the throat and ear department of the Metropolitan Hospital and consulting laryngologist and aurist to the Royal Navy, died in London on March 6, aged 60.

Mr. W. DOUGLAS HARMER sends the following appreciation: The death of Geoffrey Carte leaves a gap amongst a large circle of patients and friends. He was the son of Geoffrey Williams Carte, who was a musician and who was connected with the firm of Rudall Carte and Co., the makers of musical instruments. He was a distant relative of the D'Oyley Carte family. Geoffrey was educated at Rugby and at Oxford. Afterwards he entered St. Bartholomew's Hospital, where he was house-surgeon and later assistant in the throat department. He was an M.B.Oxon and a Fellow of the Royal College of Surgeons. After leaving St. Bartholomew's he had numerous appointments, including surgeon to the throat and ear department of the Metropolitan Hospital, the London Hospital, and St. Andrew's, Dollis Hill. In the last war he served with the Royal Navy and later as consultant to the Admiralty. At the outbreak of the present war he became a member of the Home Guard and also devoted himself enthusiastically to A.R.P. duties, in which service he was mentioned. In addition to his hospital work he carried out a very busy practice—for many years as assistant to Sir Milsom Rees, and after the latter's retirement continuing to treat a number of opera singers and actors. From his father he inherited his love of music and was a regular attendant at Covent Garden. He was a keen sportsman and spent his holidays shooting and fishing, and had many hobbies, including gardening. He had many friends, by whom he will be greatly missed. He was a well-known and popular member of the Garrick Club, and also of the Set of Odd Volumes Club. He was twice married, and leaves a daughter who is at present serving in the W.A.A.F.

Dr. HUGH MIDDLETON EYRES, formerly of Richmond, Yorkshire, died at Swale, near Keswick, on March 12. He was born in London in 1871, and educated at the City of London School, and later at Gateshead High School. He then went on to Edinburgh, graduating M.B., C.M. of the university in 1895, and completed his medical studies at Heidelberg. Dr. Eyres was in general practice at Richmond from 1898 until 1934, when he retired owing to ill-health. He had held house appointments at the Royal Infirmary and the Royal Maternity and Simpson Memorial Hospital, Edinburgh, and at Richmond was honorary medical officer to the Victoria Hospital. He was appointed a borough magistrate, and during the last war served as M.O. to the local Red Cross Hospital.

With the death of Dr. PAUL NATHAN on Feb. 19 at the age of 51 passes one of the most outstanding of the doctors who came to us as a result of the terror in Germany. In that country he devoted himself to paediatrics, where for many years he had a happy association with the famous Czerny. In private practice in the West End of Berlin he achieved a great popularity, and this with his hospital work made his life a very busy and full one. At the height of a successful career it was hard and poignant to give up, but his was not a nature to tolerate pin-pricking and humiliation, and without hesitation he left it all and became a medical student again in this country and qualified in 1938. For six years he worked in London as a children's specialist, and soon he was overwhelmed with work because with children he had amazing powers and secured the confidence of his little patients and consequently their parents' in quite a remarkable way. With British residence came also a complete British outlook, and he really loved our country. There was no looking over the shoulder with Paul Nathan save in one thing, and that was music, and at his delightful parties, where he and his wife made most perfect hosts, Brahms could be heard as nowhere else. His attitude towards his illness—hypertension and angina pectoris—was also the kind that we admire: there was no fear, no pessimism; just a heroic and cheerful defiance of it all and a desire first of all to be at his work again among his little friends and secondly to give happiness to those around him.—A. D. W.

SERVICE IN MEMORY OF LORD DAWSON

A service in memory of Viscount Dawson of Penn was held in Westminster Abbey on March 20. The assembly which filled the choir and transepts was itself a significant tribute to his personality and work. It included many holding high positions in the nation, a very large and distinguished company of members of his own profession, and representatives of innumerable organizations with which he had been in some way connected. The King was represented by Lord Wigram, Queen Mary by Lord Claud Hamilton, and Princesses Helena Victoria and Marie Louise by Mrs. Adams. The family mourners were headed by Viscountess Dawson of Penn and her three daughters, the Hon. Mrs. David Dawson-Eccles, the Hon. Mrs. Ian Bowater, and the Hon. Mrs. John Wrightson. The Prime Minister and the Chancellor of the Exchequer were represented, and the members of the Government present were Lord Simon (Lord Chancellor), Mr. H. U. Willink (Minister of Health), Sir William Jowitt (Minister of National Insurance), Mr. Ernest Brown (Chancellor of the Duchy of Lancaster), Col. Oliver Stanley (Colonial Secretary), and Major Lloyd George (Minister of Fuel and Power). The Norwegian, the Argentine, and the Netherlands Ambassadors attended. The congregation included many of Lord Dawson's fellow members of the House of Lords—Viscounts Greenwood, Lee of Fareham, and Elibank, Lords Milne, Camrose, Kemsley, Leverhulme, Courtauld-Thompson, Denham, and Hardinge of Penshurst.

The members of the medical profession, wearing their academic gowns, were headed by the President (Lord Moran), and members of Council of the Royal College of Physicians, the Chairman (Dr. H. Guy Dain) and members of Council of the British Medical Association, the President (Sir Alfred Webb-Johnson) and members of Council of the Royal College of Surgeons, and, the President (Mr. Eardley Holland) and members of Council of the Royal College ot Obstetricians and Gynaecologists. Sir Henry Dale and Dr. Gordon Holmes represented the Royal Society; Surgeon Rear-Admiral Gordon-Taylor was present with other representatives of the Royal Society of Medicine; and the Vice-Chancellor (Prof. Frank Horton) with other members of the Court were present as representing the University of London. Others who attended were Lord Horder, Sir Kaye Le Fleming, Dr. C. O. Hawthorne, Sir Herbert Eason, President of the General Medical Council, the Directors-General of the Medical Services of the Navy, Army, and Air Force, Dame Janet Campbell and other representatives of the Medical Women's Federation, Sir Farquhar Buzzard representing the Nuffield Trust, Sir Wilson Jameson and Sir Francis Fraser of the Ministry of Health, the High Commissioner of Canada, the Mayor of Westminster, representatives of the London County Council, and the Deans of King's College and Westminster Hospital Medical Schools.

In addition to many others who attended in their personal capacity, about seventy organizations apart from those already named were represented. These included the Medical Research Council, the Society of Apothecaries, the Royal Society of Tropical Medicine and Hygiene, the Society of Medical Officers of Health, the Faculty of Radiologists, the British Dental Association, the Mount Vernon Hospital and Radium Institute, the National Association for the Prevention of Tuberculosis the Ophthalmological Society, the Royal Medical Benevolent Fund, the British Red Cross Society and Order of St. John, the Professional Classes Aid Council, King Edward's Hospital Fund for London, the Hospital Saving Association, the London School of Economics, the Salters Company, the Pilgrims, the British Social Hygiene Council, and the Trades Union Congress. About thirty representatives of the nursing staff of the London Hospital attended in a body.

The service was conducted by the Dean (Rt. Rev. Paul de Labilliere) and the other clergy of the Abbey, and Archbishop Lord Lang read the lesson, which was the passage beginning "Honour a physician" from the book of Ecclesiasticus, and pronounced the benediction. There was no address. The opening sentences of the Burial Service were sung to the setting by John Merbecke. The fifteenth and a paraphrase of the twenty-third Psalm and the hymn, "Jerusalem the golden," were sung, and the choir gave the anthem, 'I will lift up mine eyes unto the hills." After prayers, one of which was for the brotherhood of the Most Honourable Order of the Bath, of which Lord Dawson was a Knight Commander, the whole congregation joined in the General Thanksgiving, after which the Nunc Dimittis was sung, and as the procession passed down the church to the west door the Requiem Aeternam, by Basil Harwood, was played on the organ. The flag of St. George flew at half-mast from one of the Abbey towers.

A service in memory of Sir Thomas Barlow was held on March 7 in the chapel of the Hospital for Sick Children, Great Ormond Street, London. Sir Robert Hutchison, in an address in thankful remembrance of the life and work of Thomas Barlow, said that this simple service in the hospital to which he was so much devoted and where much of his work had been done was a form of family worship and recollection. "It is difficult to realize that it is 70 years since he whom we have in our thoughts to-day first joined this family, when he became assistant physician to the hospital, and that he served it faithfully thereafter for a period of 25 years; and perhaps my only claim to address you this afternoon is that I had the privilege of acting as his house-physician here almost half a century ago." Copies of the address may be had from the secretary of the hospital.

Medical Notes in Parliament

Diphtheria Immunization

Mr. WILLINK furnished on March 8 totals of children under 5 and between 5 and 15 immunized against diphtheria in England and Wales. Separate figures for the year 1941 were not available, and for the year 1944 complete figures were not yet available beyond June 30.

Year	Under 5	5 to 15
1940 and 1941	547,360	1,818,030
1942	610,950	789,800
1943	525,820	513,670
1944 (first half)	173,220	93,090

Mr. Willink added that the returns on which these figures were based did not include immunizations by doctors in private practice.

Penicillin for Private Practice

Sir E. GRAHAM-LITTLE on March 8 asked the Minister of Health to release some supply of penicillin for use in civilian medical practice as distinguished from hospital practice. Mr. WILLINK said arrangements were being made for a wider distribution of penicillin from upwards of 200 large hospitals throughout the country, which would be authorized to issue penicillin on request to smaller hospitals. It would in most cases be necessary for a patient requiring systematic treatment to be removed to hospital, but each distributing hospital would be authorized to issue penicillin to private practitioners for the treatment at home or in a nursing home of suitable cases when removal to hospital was not practicable.

Women Medical Students

In replying on March 8 to Sir William Beveridge, Mr. BEVIN said that in consultation with Mr. Willink he was making arrangements whereby medical schools could provisionally consider applications from women of any age who wished to be admitted next October. Whether selected candidates would be permitted to begin their courses on that date must depend upon the national situation. Sir William, in his question, said that two of the three London medical schools were about to hold entrance examinations to select students for the first medical course starting next October, but the successful candidates over the age of 19 could not be allotted vacancies without Mr. Bevin's approval.

Penicillin Supplies in Jamaica

Sir E. GRAHAM-LITTLE reported that there was much dissatisfaction in the medical profession in Jamaica at the limitation of supplies of penicillin, and that an expert advisory committee appointed by the local branch of the B.M.A. was fully competent to ensure that all supplies reaching the Colony shall be used to the best medical advantage. Col. STANLEY said it was the case that there was dissatisfaction in Jamaica at the limitation of supplies of penicillin, but this was at least partly due to a misunderstanding as to the possibility of supply through normal commercial channels and as to the necessity for limitation of the supplies available for Colonial civil use.

It had now been possible to arrange for penicillin to be used in the Colonies subject only to the same restrictions as applied in this country. Government control of distribution was still necessary and was being exercised in Jamaica by a local committee consisting of three Government medical officers and two private practitioners nominated by the local branch of the B.M.A. He hoped that with the fuller supplies available and greater understanding of the restrictions still necessary, the causes for local dissatisfaction had been removed.

Wartime Nurseries

On March 9 Mr. McNeil opened a discussion on the future of wartime nurseries. He said 1,500 of these had been opened in England. Mr. Willink had suggested that when women with young children were no longer needed for war work, the nurseries should be discontinued or handed over to local authorities for nursery schools. He advocated their continuance. The medical officer of Smethwick had pointed to the remarkable development of the average child in these nurseries. Miss Horsbrugh replied that there was no question of closing wartime nurseries where these were attended. Where the nurseries were not attended and not required the order was that they should be closed.

Health of Allied Soldiers on the Rhine

In the House of Commons on March 13 Sir James Grigg introduced the Army Estimates. He quoted the opinion of Field Marshal Montgomery on the condition of the British Empire troops when the present offensive began in the Reichswald Forest area on Feb. 8. The Field Marshal said that they were in a very highly efficient state. The ranks were full, equipment was full scale, the sick rate was only 1 per 1,000 a day evacuated to hospital, and the troops were in tremendous form and in great spirits. Speaking of the American troops in Great Britain before the invasion of the Continent, Sir James Grigg said that we provided them with hutted camps for 800,000 and hospitals containing nearly 100,000 beds. In the coming months demands for foodstuffs for the liberated countries might become almost overpowering. The news from the areas of Holland still in German hands showed that the population were in desperate straits. In Germany there would be displaced persons by the million who would look to the armies for food. The combined resources of the Allies might be strained to the utmost to prevent hunger and, indeed, starvation, especially if our victory came before the new harvest was gathered.

Dr. Haden Guest paid a tribute to the magnificent spirit and high morale of the whole of the 21st Army Group, and to the medical services, which he inspected in the early days of February. Tremendous progress had, he said, been made in the medical service. The astonishingly small number of casualties and the high rate of recovery were a tribute to the efficiency of that service. The co-operation between the medical service and the other services was so much closer and more intimate than in the past that it had completely changed the picture of the health conditions and the vitality and vigour of the Army. The work of the hygiene services in giving all the troops a knowledge of how to keep completely fit had made an astonishing change in health and fitness. In the 21st Army Group the louse and scabies were practically unknown. Trench foot, which was the bane of operations in Belgium and the Low Countries in the last war, for practical purposes simply did not occur in the British Armies.

Medical and Pharmaceutical Equipment in R.A.M.C.

Mr. Linstead on March 15 opened the debate on the report stage of the Army Estimates by drawing attention to the supply of medical and pharmaceutical equipment in the R.A.M.C. He said that, broadly, commissions in the R.A.M.C. were reserved for medical men. The result was that the greater part of the administration of the Corps was in the hands of medical officers under whom medical equipment and stores were dealt with by Army dispensers who practically never reached commissioned rank. In this war the Army had some 800 pharmacists. Practically all were used as sergeant-dispensers and not as pharmacists. They had no real responsibility for organizing the medical stores as a whole. A number of medical men in the R.A.M.C. were being used for medical supply administration, although there was a shortage of doctors both in civil life and in the Army. Pharmacists called up from civil life were waiting six or nine months in the Queen Alexandra Hospital at Millbank or in Edinburgh or Leeds for posting as sergeant-dispensers. Weakness was also shown in equipment. There was nothing to indicate that the Army had improved its packing of drugs or surgical supplies since the last war. Drugs were supplied in paper bags to the Forces abroad. Crystal violet for burns was supplied to the Forces overseas in 1-lb. and 2-lb. lots, which had to be made into 5-g. quantities for the field ambulances. Ointments were supplied in 10-lb. and 7-lb. quantities. He heard complaints that a type of hypodermic syringe used in the Army was fitted with loose pistons, that the graduations could not be read, and that the cement with which the barrel was fixed to the nozzle crumbled. He believed the War Office feared that if the pharmacist was promoted to commissioned rank, the same would have to be done for the radiographer and the physiotherapist. The R.A.M.C. had to face the issue. Men who graduated at universities as pharmacists now went into the infantry or artillery rather than the R.A.M.C. In India a pharmacist who was a lieutenant-colonel had taken charge of the pharmaceutical supplies. The United States had its Pharmacist Corps. The Navy had a pharmaceutical service manned by pharmacists who, if they went abroad, were commissioned. The Air Ministry had recently commisisoned pharmacists as medical store officers.

Sir James Grigg, replying to the debate, said he did not think it true that there were no officer pharmacists in the Army. The organization for the supply of medical and surgical stores was officered by quartermasters of the R.A.M.C. Most of these had the Army dispensers' qualification. Many were pharmacists. The number of pharmacists who were being commissioned as quartermasters had increased. Little complaint had been made of the Army medical services in this war. They had stood up to 5½ years of war in a manner beyond praise. He did not agree that the Army required a separate pharmaceutical service, but he would examine that question in the light of memoranda which Mr. Linstead had furnished to the War Office.

Treatment in South Africa of Tuberculous Service Patients

On March 13 Sir E. Graham-Little asked the Minister of Health whether, in view of the shortage of sanatorium accommodation and staff in this country, difficulties of diet and unsuitability of the British climate, and the fact that there was a British military sanatorium in Johannesburg with more than 1,500 beds, excluding outside convalescent institutions, he would reconsider present arrangements by which tuberculous patients who had failed to respond to treatment were automatically discharged from the Services, and encourage tuberculous Service patients in every stage to seek treatment in South Africa. Sir James Grigg, who replied, said that the majority of tuberculosis cases among military patients in India and the Middle East were evacuated to South Africa to the South African Military Hospital and convalescent depot until cured or until they ceased to be infective. This procedure, however, was restricted to those patients whose condition permitted of the lengthy sea voyage involved, and who were likely to respond to treatment within a reasonable time. Other tuberculous patients in the Army received treatment in Army hospitals, and, if found unlikely to be fit for further service, were discharged and became the responsibility of the Ministry of Health.

Increase in Dysentery in Scotland

On March 13 Mr. Westwood informed Mrs. Hardie that he was aware that there had been a sharp increase during the war in the number of persons notified as suffering from dysentery in Scotland, although the number of certified deaths was stationary since 1941. Most cases were mild and involved only a few days' incapacity. The increase began long before the war, and might be partly due to improved methods of diagnosis. During 1944 there was no recorded instance of spread of the disease among the civilian population by food, milk, or water, although the possibility could not be ruled out.

Mrs. Hardie asked if Mr. Westwood was aware that this disease was caused mainly by food-poisoning, and if there was sufficient inspection of food supplies in Scotland. Mr. Westwood said that the medical officers of the Department of Health for Scotland were in close touch with the public health authorities, and the Department was watching the position very closely.

Discharge of Tuberculous Service Men

On March 20 Mr. Driberg asked the Secretary of State for War why the new rule governing the discharge from the Forces of men disabled owing to war service did not apply to those suffering from tuberculosis. Sir James Grigg: Most of the sanatoria in this country are run by the civilian authorities, and Service patients are transferred there as soon as arrangements can be made, so that they can receive the prolonged special treatment they need. These sanatoria do not admit patients who are in the Services, and they are, therefore, discharged before admission.

The Services

Temp. Surg. Lieut. G. A. Rawlins, R.N.V.R., has been awarded the D.S.C. for gallantry and devotion to duty in the care and rescue of survivors on the Assault Beach at Walcheren.

Repatriated.—Major B. B. Hosford, R.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Missing, wounded, believed to be prisoner of war.—Major R. A Murphy, R.A.M.C.

Wounded.—War Subs. Capts. W. J. Cameron and A. L. Stalker, R.A.M.C.

AUXILIARY R.A.M.C. FUNDS

The annual general meeting of the members of the Auxiliary R.A.M.C. Funds will be held at 11, Chandos Street, W., on Monday, April 9, at 6 p.m., when the annual report and financial statement for the year 1944 will be presented and the officers and auditors for the current year elected. Alteration of the rules to permit the amalgamation of the Benevolent and Relief Branches of the 1916 Funds will be considered.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* the measles epidemic continues to increase in intensity, there being 2,569 more cases reported than last week. Dysentery also continues prevalent, the total going up by 13. Whooping-cough notifications were 40 higher than last week, but those for scarlet fever were 37 fewer. Measles reached a new high level; for three weeks the notifications of this disease have been larger than for any other period since the outbreak of war. The largest rises over last week's notification figures were: Yorks West Riding 381, Durham 248, Middlesex 204, Essex 177, Gloucestershire 184, Glamorganshire 129, Staffordshire 147, Somersetshire 136, Oxfordshire 133, Warwickshire 108, Leicestershire 103.

The notifications of dysentery rose for the fourth consecutive week, and for the third time in the past six years the total exceeds 400. Fresh outbreaks during the week occurred in Derbyshire 31 (Shardlow R.D. 27), and Northamptonshire 14 (Towcester R.D. 12). The high level of incidence in London was maintained (67); the boroughs with the largest outbreaks were Wandsworth 21, Kensington 13, Paddington 11. Other large centres of infection were Yorks West Riding 34, Lancashire 32, Buckinghamshire 28, Suffolk 23, Surrey 22, Middlesex 20, Berkshire 15, Oxfordshire 13, Essex 10.

The outbreak of gastro-enteritis reported from Scotland last week appears to be spreading. Leeds has experienced a minor epidemic of sickness and diarrhoea. The causative agent is unknown, and the symptoms differ from the well-known forms of intestinal infection.

In *Scotland* for the fifth consecutive week the incidence of diphtheria rose slightly. There were 28 more cases of scarlet fever than last week but 15 fewer for measles and 26 fewer for whooping-cough. Notifications of dysentery fell by 10 but remain high; the largest returns were Edinburgh 39, Glasgow 31, Falkirk 17, Renfrew County 15. The prevalence of this disease has given rise to concern, and, replying to a question, the Under-Secretary for Scotland said that there was no record of the increase being due to infected food, milk, or water, although the possibility could not be ruled out.

In *Eire* diphtheria notifications fell by 25, but those for measles rose by 18. Cases of whooping-cough were 43 fewer than last week, and the total was the lowest since the beginning of December.

In *Northern Ireland* last week's low level of diphtheria notifications was not maintained, there being a rise of 21 cases. Measles notifications fell by 20.

Week ending March 17

The notifications of infectious diseases during the week in England and Wales included: scarlet fever 1,621, whooping-cough 1,527, diphtheria 558, measles 25,266, acute pneumonia 876, cerebrospinal fever 81, dysentery 428, paratyphoid 10, typhoid 6.

No. 10

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended March 10.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

Rate per 1,000 total births (including stillborn)			35					39		

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

There have been two nominations for the Scottish Universities Parliamentary by-election caused by the resignation of Mr. G. A. Morrison. They are Sir John Boyd Orr, M.D., F.R.S., standing as an Independent, and Mr. R. M. Munro (Lib.-Nat.), a secondary school headmaster. Polling will take place from April 9 to 13, and the result should be declared on April 14.

A meeting of the Society of Public Analysts and Other Analytical Chemists will be held at 5 p.m. on Wednesday, April 4, at the Chemical Society's Rooms, Burlington House, Piccadilly, W., when papers will be presented and discussed on the freezing-point of sour milk, the electrometric determination of ascorbic acid, and on magnetic stirring in the electro-deposition of metals.

At a meeting of the Faculty of Homoeopathy on Thursday, April 5, at the London Homoeopathic Hospital, Great Ormond Street, Dr. E. K. Ledermann will lecture on "Homoeopathy and Natural Therapeutics."

The Chadwick Trust announces a lecture by Mr. A. Trystan Edwards, F.R.I.B.A., on "Sunlight and Sanitation in Relation to the Planning of Buildings," to be given on Tuesday, April 10, at 2.30 p.m., at the Royal Sanitary Institute, 90, Buckingham Palace Road, S.W.

The Royal Sanitary Institute (90, Buckingham Palace Road, S.W.) announces the following meetings: at the Institute, Wednesday, April 11, at 2.30 p.m., Prof. S. P. Bedson, F.R.S., "Virus Diseases, the Mode of their Spread and Control"; at Loughborough, Saturday, April 14, at 10.30 a.m., Mr. W. Granger, "Rural Water Supplies—Ideals and Practical Possibilities," and Mr. H. Bintcliffe, "The Sanitary Inspector's Views on the Past and Future"; at the Institute, Wednesday, April 25, at 3.30 p.m., Mr. H. D. Manning, "Design and Construction of Sewage Disposal Works for Wartime Establishments."

The annual meeting of the Liverpool Psychiatric Clinic will be held at Liverpool Town Hall on Thursday, April 12, at 3 p.m., when Dr. C. H. Rogerson will speak on "The Place of Psychiatry in the Health Services of the Future."

The Marriage Guidance Council, whose aims and work were described in the *Journal* of March 17 (p. 377), will hold a spring meeting on Tuesday, April 24, at 6 p.m. in the Hastings Hall of B.M.A. House, with Lord Horder in the chair. The speakers will be Mrs. R. A. Butler (wife of the Minister of Education), and Dr. Charles Hill, Secretary of the British Medical Association. The title of the meeting is "Our Homes." Accommodation is limited, and admission is by ticket only (2s. each). They should be applied for in good time, from the Secretary, 78, Duke Street, London, W.1 (Mayfair 6787).

The Biochemical Society and the Nutrition Society have arranged a joint whole-day conference on the vitamin B complex, to be held on Saturday, April 28, at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1. Details of the programme will be published later. The Nutrition Society is also organizing a discussion on the nutritional factors affecting wound-healing, to take place on Saturday, May 26, at the same address.

To mark the 132nd anniversary of David Livingstone's birth, a wreath was placed on the memorial to him in East Princes Street Gardens, Edinburgh, on March 19. Dr. J. W. Arthur said that David Livingstone's name would remain fresh throughout all time as a great Scotsman and as an explorer who benefited the world by his discoveries.

The following members of the medical profession were elected Fellows of the Royal Society of Edinburgh on March 5: Robert Aitken, M.D., F.R.C.P.Ed., Prof. C. H. Browning, M.D., F.R.S., Prof. Archibald Durward, M.D., Abdul Ghaffar, M.B., Ph.D., John Jardine, O.B.E., M.D., F.R.C.S.Ed., D. D. Logan, D.S.O., M.D., and Robert Walmsley, M.D.

The Council of the Royal Society of Medicine a few months ago decided to extend the visitors' privileges which could be enjoyed in the Library. Hitherto it had only been found possible to allow a visitor into the Library for seven visits. Circumstances having now changed the Council has made the library of the Society virtually an "open" one, at least for an experimental period of six months. This period is now running and appears to be very successful. A room is set apart on the second floor for the exclusive use of visitors, with a member of staff in attendance who brings the books and documents of which they are in need. In this way the work of the main library is not disturbed, and those who need the help of the Library occasionally without becoming Fellows of the Society are enabled to have this assistance. The experimental period for which this room is open comes to an end at the beginning of June, when results will be reported to the committee so that the scheme may be altered in whatever way is indicated by experience.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Cancer not Contagious

Q.—*A woman who has children wishes to live with a patient suffering from inoperable ulcerating carcinoma of the cervix and vaginal wall, but is anxious about possible danger to the present or future health of her children. Should they live in the same house?*

A.—Cancer is non-contagious. Even those tumours which are known to be caused by a virus do not spread. For example, a chicken suffering from a virus sarcoma can be kept in a pen with normal chickens, and the normal chickens never contract sarcoma. The non-contagiousness of the disease is even stricter than this: although virus can at times be obtained from the blood of chickens, infection of normal cells does not occur within the body of the animal suffering from sarcoma. There is no reliable evidence that human or mammalian cancer in general is caused by a virus, and certainly no evidence that the disease is contagious. Every sound investigation of the so-called cancer houses or cancer villages has proved that the apparent increased amount of cancer is either not true or if true is explained by an excess of old people in the community. It can be said that cancer is no more contagious than broken legs. Therefore it is safe to advise that the children will come to no harm now or in the future if they are taken to live in the same house as the unfortunate lady.

Calcification in Supraspinatus Tendon

Q.—*What treatment do you advise for a painful shoulder due apparently to a small area of calcification in the supraspinatus muscle, as shown by x rays? If x-ray treatment is advised, what is the dosage? Is massage advocated, and is active movement helpful? Are there any articles of diet to be avoided?*

A.—Pain in the shoulder associated with skiagraphic evidence of calcification in the tendon of the supraspinatus is a well-recognized condition, and was first described by the American surgeon, Codman. There is now no doubt that the essential lesion is damage to the tendon, which may be the result of injury but occurs not infrequently in its absence. Apparently the tendon of the supraspinatus (like that of extensor pollicis longus) may degenerate with advancing years simply as a result of the trauma of normal use. The calcification is secondary. The exact cause of the pain and stiffness is a little obscure, but it seems likely that the calcareous deposit produces a subacromial bursitis; excision of the calcified area generally relieves the pain, though some weakness of abduction may remain as a result of the poor condition of the supraspinatus tendon. It has recently been found that the deposit can be broken up and to some extent washed out by irrigation of the calcareous mass through one medium-bore aspirating needle, and by suction through another slightly larger needle introduced alongside the first. In order to render the procedure more or less painless it has been customary first to inject novocain. Then it was discovered that the novocain injection alone often gave complete and lasting relief, even though subsequent radiographic examination showed little or no change in the appearance of the deposit. Why this should happen has not been satisfactorily explained.

The treatment should therefore be: (1) Widespread novocain injection (0.5% with 1/200,000 adrenaline) of the superior capsule of the shoulder-joint. If the pain is completely relieved the patient must move the joint through the fullest possible range during the two hours following the injection, and at regular intervals—say, three times a day—for one week after. (2) If novocain injection fails, irrigation and aspiration may be tried: the solution as before; after-treatment the same. (3) As a last resort the tendon should be explored through the standard anterior incision.

The writer has no experience of *x*-ray treatment for calcification of the supraspinatus tendon; massage is not indicated; and there is no indication for dietetic restrictions.

Haemorrhagic Disease of the Newborn

Q.—*A patient has had two female children. The first is stated to have had marked icterus after birth but has developed into a healthy girl of 6. The second child appeared normal at birth, but when ten days old developed signs of haemorrhage; haematemesis, and melaena, from which it died. The patient is expecting a third child. Would vitamin K given to the mother at the end of pregnancy and to the child soon after birth be advisable? Is it probable that the Rhesus factor is at work in this case, and if so, what can be done about it? Both parents are healthy and there is no history of any familial disease.*

A.—This history is not highly suggestive of trouble arising from Rh incompatibility and the data are not sufficient to establish the diagnosis. In a first child jaundice terminating in complete recovery is more likely to be physiological icterus than icterus gravis; when first children are affected hydrops foetalis is more probable. The second child had chiefly haemorrhagic manifestations, and although 10 days after birth is late for the onset of haemorrhagic disease of the newborn, this seems the most probable diagnosis and is an indication for administration of vitamin K to the mother at the end of pregnancy. Since vitamin K rapidly passes into the foetus *in utero*, further administration after birth is unlikely to be needed.

Rh tests should be carried out on mother, father, and surviving child, if possible with determination of genotypes. If Rh incompatibility exists, and especially if there is anti-Rh agglutinin or its incomplete form in the mother's serum, arrangements should be made to examine the infant's blood immediately after birth; if haemolytic disease is shown by the presence of erythroblastosis, etc., the baby should at once be transfused with blood of the same Rh type as the mother. Transfusion of blood is the only remedy of value in Rh cases, but the choice of what kind to give depends on the results of tests on the *mother's* blood, not on the baby's, as what is wanted is blood that will not be harmed by whatever antibody the *mother* may have transmitted to the child. The tests can usually be carried out by the Regional Transfusion Officer.

Age and Caesarean Section

Q.—*Is age an indication for Caesarean section? Should it be done, for example, in a healthy woman aged 42 having her first baby?*

A.—It would be unwise to attempt to lay down a rule to cover every case, but in general it can be stated that the age of a patient in itself does not constitute an indication for Caesarean section. Many women aged 40 and over have rapid and easy deliveries. The factor which is more important than age is the number of years of infertility which have preceded the pregnancy. Thus, if a woman of 42 has been trying to conceive for 10 years before she was successful, then the prospects of a difficult labour (mainly due to faulty uterine action) are considerable. Moreover, she will have little chance of conceiving again. If, however, the woman married late and conceived readily then an easy labour is to be expected. In any case there is much to be said for a trial of labour, with a lower-segment section if progress is not satisfactory, rather than a set operation before the onset of labour.

The presence of any abnormality alters the picture, and conditions such as breech presentation, inertia, etc., which in younger women would be treated conservatively, are often best dealt with by Caesarean section when the patient is an elderly primigravida.

Anaesthetic for Quinsy Excision

Q.—*What is the best anaesthetic to use for the incision of a quinsy when working single-handed?*

A.—This depends on whether there is any respiratory obstruction, as from oedema of the glottis, or not. The management of anaesthesia in the former case is dealt with in Macintosh and Bannister's *Essentials of General Anaesthesia* (Blackwell), page 268. If there is no obstruction the practitioner could give the anaesthetic with which he is most familiar. Loss of laryngeal reflexes from cocaine or deep general anaesthesia should be avoided, and the patient's head should be well extended to ensure that blood and pus do not enter the larynx.

Reversing Operation for Vasoligature

Q.—*In reference to the question and answer on bilateral vasoligature in the* JOURNAL *of Feb. 24 (p. 283) is there any risk of testicular atrophy? If there is not, is it possible by subsequent operation to restore the channels of the vas deferens and so fertility?*

A.—There is no risk of testicular atrophy provided the vasoligature is skilfully done, since it does not affect the testicle's blood supply. On one occasion I have been asked to restore the patency of vasa previously ligatured. As spermatozoa reappeared in the semen, but in small quantities, it may be assumed that the operation was successful—at any rate, on one side. Bilateral vasoligature should, however, be regarded as being an irreversible operation, because a successful reunion of the divided ducts cannot be guaranteed.

Transfusion

Q.—*There are two schools of thought in intravenous therapy: those who never give more than 3 litres in 24 hours, and those who give it to replace fluid loss and judge the amount by urine output and chloride content, etc. May I have advice?*

A.—The rate at which fluid is administered by the intravenous route must depend upon the reason for which it is given. Following traumatic injury fluid must often be given very rapidly, perhaps one litre in half an hour, followed at a somewhat slower rate by further large quantities of fluid. Factors controlling the rate of administration are the degrees of injury, the blood pressure, pulse, and general condition of the patient. The object should be to keep and maintain the blood pressure above 100 mm. of Hg. The amount given in any case can be decided only by the medical officer in charge. No rules for dosage can be given. In the case of a patient who is dehydrated and requires fluid, it is usual to administer it at a slower rate; 3 litres in 24 hours for this purpose is probably reasonable.

Yaws and Wassermann Reaction

Q.—*I see numerous Javanese, Goanese, and British Indian seamen who are walking pathological museums. I begin with a worm-killer of chenopodium and tetrachloride. The rate of positive Wassermanns is about 35%. Occasionally there are tissue-paper scars on the legs which may have been yaws or the common tropical ulcers, but several have positive Wassermann reactions in their cerebrospinal fluid. The history of V.D. and yaws is most variable. But, as we found 2% rate of positive Wassermanns in European sailors who have never seen any clinical signs, the problem is one of interpretation. What treatment, if any, should be instituted considering the terms of their contract with the shipping companies?*

A.—A combination of 1 c.cm. ol. chenopodii and 2 c.cm. carbon tetrachloride in an ounce of liquid paraffin, followed in one hour by a sharp saline purge, has proved reasonably safe, effective, and convenient in the routine treatment of intestinal helminthiasis among native populations. Yaws, unless treated efficiently, does not retrogress or vanish, but becomes chronic and intractable. If untreated it would therefore be clinically obvious for the remainder of the patient's life. Healed scars on the legs of native peoples are common and are usually due to trauma and to secondary infections of various kinds; in the absence of a history of yaws, which the native knows well, and of early specific and effective treatment of the condition, such scars cannot be attributed to past yaws. A positive blood Wassermann reaction in a patient without active lesions of yaws must therefore be taken as indicative of a syphilitic infection. Yaws does not attack the central nervous system; and examination of the cerebrospinal fluid from many cases of yaws shows almost all of them to be Wassermann-negative. So a positive Wassermann reaction in the cerebrospinal fluid is presumptively of syphilitic origin. It is established that tertiary syphilis, with cerebrospinal fluid changes, does develop in men who have no recollection of either primary or secondary manifestations of the infection.

Barrier Creams and Detergents

Q.—*Can you recommend (a) a suitable barrier cream, and (b) a suitable detergent for a man liable to attacks of lubricating-oil dermatitis (ordinary heavy greenish oil). Can these preparations be made up easily by a pharmacist? If not, who would supply them?*

A.—(*a*) There are a number of barrier preparations which would be suitable for protection against cutting oils: further information could be obtained from H.M. Senior Medical Inspector of Factories, 12, St. James's Square, London, S.W.1. Barrier creams are not easy to dispense, but some manufacturing chemists have had considerable experience in preparing barrier creams, the detailed formulae for which are not generally revealed. (*b*) A cleansing agent for those working with oils is sulphonated castor oil with 5% industrial methylated spirit and 2% wetting agent. Wholesale chemists should be able to supply this. Special care, depending on circumstances, is indicated for those who have had previous dermatitis, but in general terms washing with soap and water should follow the use of detergents. A skin food may be useful after work.

Death from Varicose Vein Injections

Q.—*I have heard it said that people have died during the injection treatment of varicose veins. Is this true?*

A.—Yes, a number of deaths have been reported after the injection of varicose veins, particularly after the injection of sodium morrhuate. This preparation is a variable chemical composition and does cause anaphylactic shocks from time to time, varying in degree from slight to fatal. I have heard of no deaths occurring after the use of quinine urethane or after ethamolin; but obviously, if excessive doses are used, even these substances would prove toxic.

INCOME TAX

Expenses while Serving in the Forces

T. A. has held various administrative posts in the R.A.M.C. since the outbreak of war. Can he claim an allowance for expenditure on new editions of textbooks and subscriptions to the *R.A.M.C. Journal*?

*** The expenses cannot be deducted from R.A.M.C. pay, as they are not required by the War Office to be incurred. We consider, however, that they may properly be claimed as deductions from any income that may be accruing from his civil practice.

Succession to Whole of Practice

J. W. was a third partner in a practice until his father died in November, 1943, when he became the sole proprietor. He is being charged tax for the year to April 5, 1945, on the full amount of the profits of the practice in 1943. Is this correct?

*** Yes. It is necessary to remember that an assessment is based upon the profits for the previous year of the business or practice, and the assessment so calculated is then divided between those entitled to participate in the profits of the year of assessment. Thus the assessment for 1944–5 in this case is based on the profits of the practice in 1943–4, and as J. W. is the sole proprietor for 1944–5 he has to shoulder liability for the tax on those profits. If any other view were taken presumably his father's estate would have to account for tax on 2/3rds of the assessment—and at standard rate. If the amount of the profits (after payment of an assistant's salary, if any) for 1944 is less than the amount for 1943 J. W. can apply for an adjustment accordingly.

The "Employer's" Car

J. C. was employed up to June, 1942, as an assistant supplying his own car; he then moved to another town, sold his car for £25, and was working for another principal who found a car for his use. He has now become a partner in the practice but continues to use his "employer's" car. Can he claim any allowance for the loss on the old car (£50, written down value less £25 cash received) if he buys a car for, say, £200?

*** In view of the change in the nature of the income and of the interval of time since the former car was disposed of we doubt whether our correspondent has a valid claim in law, and in any case any element of improvement as between the two cars would have to be excluded. Further, if a claim to regard the new car as a renewal of the car is made, then no claim for depreciation can be made for the year following that in which the renewal expense is deducted. If a renewal claim is not made depreciation should be claimed specifically as from the date of purchase of the new car.

LETTERS, NOTES, ETC.

The Albino and the Swallow

Dr. K. SHALLCROSS DICKINSON writes: I don't know anything about the Acharnians (Aristophanes), but I *do* know (as Cmdr. Campbell might say) that when I was a boy at Chester, somewhere about 1906, a missionary thrilled us all, during a talk of his experiences, by showing us how he had had to learn to drink a ceremonial beaker with the headman of certain tribes (African, I think) at a single draught and without "moving his swallow" (see *B.M.J.*, Feb. 3, p. 174). He took a half-pint tumbler of water, put his head well back, and poured it down his throat exactly as though he were pouring it down a drain. Many times since then have I thrown back my head, and imagined that I have opened the way to my gullet and closed my trachea, but not yet have I had the courage to see whether much less than a tumblerful of liquid would "go the right way" without swallowing. Perhaps someone with more courage will try it out?

*** In the Pyrenees it is the customary way of drinking wine from a gourd.—ED., *B.M.J*

Phlebitis Migrans

Dr. J. E. O'LOGHLEN (London, W.1) writes: I have always understood that phlebitis migrans (see *Journal*, Feb. 3, p. 171) was associated with sepsis and occurred in veins that are not varicose. The veins affected are the superficial veins of the arms and legs, and sometimes the condition extends to the skin of the abdomen, where it appears as plaques and cords about 3 or 4 in. long. The inflammation remains for two or three weeks, and then regresses to recur later. The deep veins are not affected. Sepsis is always present —teeth, tonsils, etc. No bacteria have been isolated in the affected veins—suppuration does not occur. Fever is always present, and often there are initial rigors. The temperature usually subsides in 24 hours. The points of infection are very sensitive on pressure and are at first bright red in colour. The disease is not associated with disturbance of circulation. The inflammation spreads from without in, and it is only when the intima is affected that thrombosis occurs. It is thought to be a toxicosis—the toxin developing from some septic focus and accumulating in the skin. Treatment consists in removing the septic focus—often difficult to locate. Excellent results have been obtained with *x* rays to the spleen—applied on six successive days—twice on the back, twice on the front, and twice on the left side.

Recurrent Phlebitis

Mr. J. T. EDWARDS, M.R.C.V.S. (Wilmslow) writes: Referring to Dr. A. J. Colby Tingey's letter (Feb. 17, p. 246), should not chilblains be added as a source of infection leading to phlebitis? I was recently affected with phlebitis during the sloughing stage of severe chilblains on two toes of the foot of the same side. Attempts to find a septic focus in teeth and elsewhere all failed.

Treatment of Chronic Malaria

Major C. M. RIGBY, R.A.M.C., writes: I was very interested in Prof. D. B. Blacklock's letter (Nov. 18, 1944, p. 67) on the treatment of chronic malaria. During the last war I was in India and a patient of mine contracted a double infection of benign and malignant malaria. I tried every form of treatment—quinine by mouth, intramuscularly, and intravenously, and even a "quack" remedy advertised in the local Indian paper—but all without permanent removal of the parasites from the blood. Fortunately at that time I saw in the *Medical Annual*, 1917, an excerpt from an article by G. W. P. Dennys in the *Indian Medical Gazette* (July, 1916, p. 242), advocating the following:

℞	Ferri et ammon. cit.	gr. iij
	Quin. sulph.	gr. j
	Acid. arsen.	gr. 1/60

One dose a day was taken after food, gradually working up to four if possible, and continuing, if necessary, for two to three months. The patient referred to had no recurrence of malaria after a course of this treatment, and I have since recommended it to patients who have suffered from chronic malaria, with considerable success.

The Examiner's Attitude

Mr. H. I. DEITCH, M.S., F.R.C.S., writes from Halifax General Hospital: In his letter (March 3) on ovariotomy or Caesarean section Prof. S. J. Cameron raised a more important point than that of the slight difference of opinion as to two opposing lines of practice—i.e., the attitude taken by examiners for higher degrees, and particularly diplomas—and examinees are badly prejudiced who advocate what is sound practice but which may not be the pet method or theory of the examiner. A friend recently sitting for the M.R.C.O.G. was asked in one *viva* whether he would use Kjelland's forceps. He stated he would not for various reasons, and that he was able to obtain equally good results by using orthodox forceps, which was his own practice. The examiner disagreed and was unnecessarily rude into the bargain. At the next examination the same question was asked by a different examiner, and my friend, hoping that he had profited by what he had heard on the previous occasion, gave the answer accordingly. This time, unfortunately, the examiner did not approve of Kjelland's forceps, and he, too, was unnecessarily astringent in his remarks. Behaviour such as this discredits the examination and leaves a bad taste behind; it also explodes the myth that the examiners are "eminent authorities." When I sat for the English Fellowship in 1927 I was warned not to mention plaster-of-Paris in the treatment of fractures, as this in itself was sufficient to justify failure at the hands of the many elderly gentlemen then examining.

Case of Peritoneal and Pleural Effusion

Dr. E. MONTUSCHI (Sidcup) writes: The case of polyserositis described (*Journal*, Feb. 17, p. 245) cannot be due to constrictive pericarditis, neither to any other steadily progressive disease. By far the most common cause of the condition, and the most likely in the case described, is a tuberculous infection. It is to be hoped that the questioner has not hastened to submit his patient to the ordeal of oesophagoscopy, barium meals, and other irrelevant and unnecessary procedures suggested by your answerer. A consultation with the tuberculosis officer is instead indicated.

Medical Aphorisms

Dr. T. LIONEL CRAWHALL, Watlington, Oxford, is collecting medical, surgical, and gynaecological aphorisms with their sources, and would be grateful to any colleagues for help in this project.

*** The only collections we know of, apart from the classical Aphorisms of Hippocrates, are Dr. Samuel Gee's *Medical Lectures and Aphorisms*, of which the fourth edition appeared in 1915, and Dr. J. A. Lindsay's *Medical Axioms, Aphorisms and Clinical Memoranda*, published in 1923. Dr. Gee's aphorisms were taken down by one of his house-physicians, who is now Lord Horder.

CONTROL OF INFECTION IN RECENT WOUNDS BY SURGERY AND LOCAL CHEMOTHERAPY

BY

F. H. BENTLEY, F.R.C.S.
Lieut.-Col., R.A.M.C.

AND

SCOTT THOMSON, M.D.
Major, R.A.M.C.

(Penicillin Control Team, Central Mediterranean Force)

In the present organization of war surgery wounds are treated by a two-stage operation. At the first operation, at a casualty clearing station, contaminated and grossly damaged tissues are removed, and the wound is laid open so that there is free drainage, with an absence of tension, while the patient is being evacuated to the base. Several days later the wound is examined in hospital and is sutured if possible.

The main object of the first operation is the control of infection, and the subsequent progress of the case is determined by the success with which this object is achieved. No one with experience of war wounds will deny that adequate surgery at the first operation is of paramount importance. After surgery is completed, however, some degree of infection is likely to remain, and it is in connexion with this residual infection that a bacteriostatic may be of value. Although sulphonamides have been in use for many years, evidence of their true worth in the control of infection in wounds has never been obtained. With the advent of penicillin it was of increased importance to decide, by a large-scale clinical trial, the precise value of these two bacteriostatics in the treatment of recent wounds.

Evidence of the comparative effects of penicillin–sulphanilamide and sulphanilamide alone as bacteriostatics was given by Thomson (1944), from observations made during the invasion of Sicily. In 85 wounds operated upon at casualty clearing stations and treated with sulphanilamide powder 57% were infected on arrival at the base several days later; whereas in 61 wounds that had received penicillin–sulphanilamide powder 26% were infected.

This survey was a limited one. It was necessary to carry out a more extensive inquiry in which comparison was also made with wounds not treated with a bacteriostatic. The battle for the Gothic Line provided the opportunity. This battle was fought in wet weather on cultivated ground. Casualties were heavy and casualty clearing stations were working under pressure. The treated wounds were therefore a fair sample of what could be expected from experienced forward surgeons under battle conditions. The difficulty of comparing one type of case with another was simplified, since all external conditions such as terrain, weather, forward surgeons, lines of communication, and base surgeons were the same throughout the period of this inquiry.

The purpose of this investigation was to determine the value of sulphanilamide and penicillin when applied locally in the treatment of recent wounds. In the course of the inquiry information was also obtained of other factors in wound treatment—in particular, the importance of the interval between wounding and the first operation, and of the re-dressing of wounds between C.C.S. and base hospital.

Methods

The casualties from the battle were sent from C.C.S.s to a port, and were conveyed by ship to the hospital area, arriving about the fifth to seventh day after injury. Within the next day or so they were taken to the operating theatre and the wounds were examined and sutured if possible. The following data were considered relevant:

1. *Interval before Operation at C.C.S.*—This could usually be obtained from the field medical card or by inquiry from the patient. Only cases in which it was possible to determine the interval with accuracy were included in the assessment of this time interval.

2. *Chemotherapy at C.C.S.*—It was arranged with forward surgeons at the start of the battle that penicillin–sulphathiazole powder would be applied to wounds alternately with sulphanilamide, and that in a number of cases no bacteriostatic would be employed. There were therefore, initially, three groups of cases, depending on the wound chemotherapy. In addition there was eventually a fourth group comprising those cases in which no entry was made on the field medical card and which were most probably treated with sulphanilamide. It was found convenient for the purposes of tabulation to include with this fourth, or "miscellaneous," group a number of wounds that had been dressed with an antiseptic—e.g., acriflavine or sulphathiazole–proflavine powder. It should be stated at the outset that the casualties in which no bacteriostatic was employed were carefully watched along the lines of communication and at the base hospital. In no case was the wounded part endangered by this omission, and there was no instance of spreading sepsis.

3. *Age of Wounds at Time of Examination and Suture at Base Hospital.*—This information was readily available, and was measured in days.

4. *Severity of Wounds.*—Wounds were divided into three classes:

Class A.—Gutter wounds of skin and fat alone, or with superficial muscle injury.

Class B.—Wounds with penetrating tracks; or through-and-through wounds with deep muscle injury, sometimes associated with a minor fracture.

Class C.—Large lacerated wounds with extensive muscle destruction; amputations; or major fractures.

5. *Condition of Wound.*—The clinical appearance of the wound was noted and a swab was taken for bacteriological examination at the time it was first examined in hospital. It is convenient to describe here the terms employed in collecting material for this report.

"*Clean.*"—A clean wound was one that had the naked-eye appearances of a wound recently operated upon and showed no reactive changes.

"*Dirty.*"—A dirty wound was one in which the surface was covered by tissue exudates.

"*Infected.*"—The term "infected" indicated only the presence of pyogenic cocci in a wound—*Staph. pyogenes aureus* or *Str. pyogenes*.

"*Septic.*"—Those dirty wounds that were infected with pyogenic cocci were called "septic." About half the dirty wounds came into this category.

4396

6. *Dose of Sulphanilamide by Mouth.*—Tablets of sulphanilamide were given to many of the wounded men at the C.C.S. and during the period of travel to hospital. Administration of the drug and entries on the medical cards were irregular. Further information was obtained by questioning the patients; but, even so, the data often remained incomplete.

7. *Re-dressing of Wounds.*—The majority of wounds had not been touched or disturbed in any way between the operating theatre in the C.C.S. and examination in the base hospital theatre. Such wounds are discussed separately in the report. A number of wounds, however, had been re-dressed; evidence was obtained to show that it was not necessarily the septic wounds that had been subjected to this intervention.

8. *Bacterial Flora.*—The swab was taken from the surface wound and any deep track, without touching the skin edges. A wound-swab was accepted as the best method of obtaining a representative sample of the bacterial flora and of providing a qualitative examination of obvious wound infection. The energies of the laboratory were directed towards isolation and precise identification of pyogenic cocci, but with sufficient attention to other bacteria to establish at least their bacteriological group. All strains of *Staph. pyogenes aureus* and *Str. pyogenes* were examined for the property of resistance to penicillin. In addition to this examination of wounds on arrival at the base hospital, swabs were taken from 100 wounds at a C.C.S. before operation was begun in order to determine the original rate of infection in this battle. The swabs were examined by Major H. E. Hutchinson, of No. 1 Mobile Bacteriological Laboratory, to whom we are indebted.

9. *Result of Suture.*—The majority of wounds were sutured at the time of their first examination in the operating theatre at the base hospital. Penicillin was given as a routine either by insufflation of penicillin–sulphathiazole powder at operation or by subsequent instillation of a solution of penicillin through tubes into the sutured wound. The results were expressed in terms of percentage of wound union. It was obviously not possible to determine the figure with a high degree of accuracy, and in assessing the results of suture only three grades were adopted: Grade I, 85% union or better; Grade II, 70 to 85% union; Grade III, less than 70%.

Value of Chemotherapy in Control of Infection

Staph. pyogenes aureus was found to be by far the most common pyogenic coccus. *Str. pyogenes* (haemolytic streptococcus) was isolated from 6% of all wounds, and from only 1.5% in the absence of the staphylococcus. In the 100 wounds from this battle that were examined in the operating theatre at a C.C.S. before operation was begun pyogenic cocci were found in 51 (figures provided by Major Hutchinson). This was the basic infection rate which surgery and chemotherapy had to combat, and the figure with which to compare the results of treatment. These results were studied in 706 wounds in which the dressing had not been disturbed between the operating theatre at a C.C.S. and examination in the base hospital. In wounds treated at C.C.S.s the rates of infection according to the chemotherapy previously employed were:

Operation only, without bacteriostatic: 49% of a total of 116 wounds were infected.

Operation and sulphanilamide powder: 43% of a total of 213 wounds were infected.

Operation and "miscellaneous" chemotherapy: 40% of a total of 122 wounds were infected.

Operation and penicillin–sulphathiazole powder: 25% of a total of 255 wounds were infected.

Thus operation alone did not appreciably reduce the incidence of infection compared with the infection rate before operation, and the introduction of sulphanilamide into the wound produced little further improvement. The use of penicillin–sulphathiazole powder, however, caused a significant reduction in infection rate to one-half of the pre-operation figure.*

It was necessary to inquire whether this difference was due to selection of special cases for penicillin treatment; in particular, whether the apparent advantage of penicillin might be due to its having been used for selected wounds and for those coming under treatment early. The significance of the time at which a wound was first operated upon is discussed below. At present it can be stated that penicillin–sulphathiazole showed an advantage over sulphanilamide irrespective of the time the wound came under treatment. It was possible also to demonstrate that the severity of the wound did not influence the relative rates of infection. If the wounds were classified according to their severity it was seen that, while more of the large and serious wounds received penicillin–sulphathiazole powder, the reduced incidence of infection following penicillin treatment occurred equally in superficial trivial wounds and in extensive ones. There was no tendency for the result to be influenced by the severity of the wound.

Wound Sepsis

It is emphasized that the above figures refer to rates of infection as determined by a bacteriological examination of the wound. There was no correlation between the clinical appearance of the wound and the presence of pyogenic cocci, many clean wounds containing *Staph. pyogenes aureus* and many dirty wounds yielding no pyogenic bacteria on culture.

Of the undisturbed wounds 20% were dirty, being covered with exudate, and about one-half of these contained pyogenic cocci (septic). The septic wounds were of special importance in this investigation into the control of infection because they were the wounds in which the infecting bacteria had "taken hold." Of the wounds treated by operation alone and without a bacteriostatic, 23% were septic; in those in which sulphanilamide was locally employed this incidence was reduced by one-half (11%); and in those treated with penicillin–sulphathiazole 7% of the wounds were septic (Table I).

Table I.—*Rates of Infection and Sepsis in Relation to Chemotherapy*†

	No.	Infected (%)	Septic
Penicillin-treated wounds	255	25	19 (7%)
Sulphanilamide-treated wounds	213	43	23 (11%)
Wounds untreated with a bacteriostatic ..	116	49	27 (23%)

The precise value of operation and local chemotherapy in this series of wounds can thus be stated in the following terms. Operation alone, without the use of a bacteriostatic, did not appreciably reduce the incidence of infection compared with the original infection rate that followed wounding. This is what would be expected, for unless a mutilating excision was performed not all potentially infected tissues would be removed. The aim of the forward surgeon is to remove only those tissues that are grossly damaged, and by adequate incisions to leave the wound in the best possible condition for dealing with the infection that remains. The value of this treatment is seen in the wounds that were treated by operation only; although one-quarter of them were septic, the sepsis was confined to the surface layers of the wound, and there was no instance of the septic process spreading along the limb or tracking deeply.

Sulphanilamide applied locally had a bacteriostatic effect; for, although the infecting bacteria persisted, their activity was depressed, so that the incidence of sepsis was reduced compared with wounds in which no bacteriostatic was employed. Penicillin–sulphathiazole powder had a greater effect, for its use was followed by the destruction of the pyogenic organisms in one-half of the infected wounds and by an equally low incidence of sepsis.

It is obviously of value to use sulphanilamide or penicillin–sulphathiazole powder at the operation at the C.C.S., and of the two bacteriostatics penicillin–sulphathiazole is shown to be the more potent.

Effect of Re-dressing of Wounds on the Infection Rate

Of 869 consecutive wounds examined 163 had been re-dressed between operation at the C.C.S. and examination in the operating theatre at the base hospital. If these wounds had been re-dressed because they were septic, it would be expected that they would include a large proportion still septic on examination at the base hospital. This was not found to be so, as only 15% were septic, which is an incidence of sepsis no greater than that shown by the general series of undisturbed wounds. (Table I). If the re-dressed wounds were classified according to their severity the following distribution was found:

---

* The difference in incidence of infection between wounds treated with penicillin–sulphathiazole powder and any of the other three groups exceeds three times its standard error. There is no significant difference between the other three groups.

† The difference in incidence of sepsis between wounds untreated with a bacteriostatic and those receiving sulphanilamide or penicillin exceeds three times its standard error. The difference between penicillin- and sulphanilamide-treated wounds is not significant.

Class A (superficial wounds): 122 wounds = 25% approximately of all Class A wounds.
Class B (deep penetration): 41 wounds = 12% approximately of all Class B wounds.
Class C (deep and extensive wounds): None.

It appeared, therefore, that the more accessible wounds had been selected for dressing.

The re-dressed wounds were found to have a higher incidence of infection than had wounds which had not been disturbed during evacuation of the patient. In 67 re-dressed wounds treated originally with penicillin–sulphathiazole powder the infection rate was 42%, compared with 25% in undisturbed wounds; and where the original treatment had been with sulphanilamide the incidence was 55% of 60 wounds, compared with 43%. The importance is confirmed of sealing off the wound with an occlusive dressing at the end of operation at the C.C.S., and of refraining from further dressings, in the absence of obvious complications, until the patient is in the operating theatre at the base hospital.

Significance of Time of Operation in Control of Infection

In the history of a wound there are two intervals of importance—the number of hours that elapse between wounding and operation at the C.C.S., and the number of days before the second operation in the base hospital.

It had already been found that the rates of infection were influenced by the use of different bacteriostatics and by re-dressing of the wounds. These two conditions had therefore to be taken into account in considering the importance of a third factor—the time of operation. This was done by showing in the 706 undisturbed wounds the relation between infection and time intervals in each of the chemotherapy groups. The following terms are employed:

"Early C.C.S.": An interval of 12 hours or less between wounding and operation at C.C.S.
"Late C.C.S.": An interval of 12 to 24 hours between wounding and operation at C.C.S.
"Early Hospital": An interval of 5 days or less to time of examination of wound in hospital.
"Late Hospital": An interval of more than 5 days to time of examination of wound in hospital.

The time of arrival at the base hospital was not related to the time of the first operation.

Incidence of Infection According to Time of Arrival at Base Hospital.—There was no significant difference in infection rate between wounds admitted to the base hospital in the first 5 days after wounding compared with those admitted late. This finding is not brought forward to suggest that delay in evacuation is unimportant. It indicates, however, that if the forward treatment is completed and the wound is sealed off, infection does not readily gain access or develop during the following 10 days.

Incidence of Infection According to Time of First Operation.—There was a lower incidence of infection in wounds that had been operated upon in under 12 hours compared with those that had been treated between 12 and 24 hours, in all the chemotherapy groups. The figures of comparison are presented in Table II.

TABLE II.—*Incidence of Infection According to Time of First Operation*

Treatment	No. of Infected Wounds	
	Early C.C.S.	Late C.C.S.
Penicillin-treated	27 out of 150 (18%)	24 out of 63 (38%)
Sulphanilamide-treated ..	38 out of 108 (35%)	35 out of 66 (53%)
No chemotherapy	29 out of 64 (45%)	18 out of 35 (51%)
Total	94 out of 322 (29%)	77 out of 164 (47%)

This table summates the figures of Early and Late Hospital.

There was thus a marked difference in infection rate according to the interval between wounding and operation. One of the features of the organization of surgery in this war has been the efforts to take surgery speedily to the wounded man, and it is of particular interest to confirm the value of early surgery in the control of wound infection.

Advantage of Penicillin over Sulphanilamide in the Different Age Groups.—It is convenient here to consider whether the advantage of penicillin–sulphathiazole powder over sulphanilamide in the control of infection occurred irrespective of the time that the wound came under treatment. To make this comparison the incidences of infection after the use of the two bacteriostatics are shown side by side in the four possible age groups.

(*i*) *Early C.C.S.: Early Hospital*

Penicillin-treated wounds	4 infected out of 44 (9%)
Sulphanilamide-treated wounds ..	10 " " 32 (31%)

(*ii*) *Early C.C.S.: Late Hospital*

Penicillin-treated wounds	23 infected out of 106 (22%)
Sulphanilamide-treated wounds ..	28 " " 76 (37%)

(*iii*) *Late C.C.S.: Early Hospital*

Penicillin-treated wounds ..	5 infected out of 17	(Figures too small for comparison)
Sulphanilamide-treated wounds ..	6 " " 17	

(*iv*) *Late C.C.S.: Late Hospital*

Penicillin-treated wounds	19 infected out of 46 (41%)
Sulphanilamide-treated wounds ..	29 " " 49 (59%)

In each age group penicillin–sulphathiazole-treated wounds had a lower infection rate than had wounds treated with sulphanilamide. The results claimed for penicillin–sulphathiazole powder are thus shown to be valid irrespective of the time the wound came under treatment.

Effect of Sulphanilamide by Mouth

Entries in the field medical card showed that nearly all the wounded men received 2.5 g. of a sulphonamide at the advanced dressing station. Thereafter, administration of the drug and entries in the records were irregular. Although many patients were questioned about taking the tablets, the available information remained incomplete. Few of the men had a full course of the drug, but records were obtained of 127 men who had received 7.5 g. or more and whose wounds were undisturbed. The incidence of infection and that of septic wounds in these patients were the same as in the general series.

Relation Between Infection and Results of Suture

So far in this report the incidence of infection has been used to measure the value of the different factors that were under investigation (bacteriostatic, time of operation, etc.). This infection is of more than laboratory interest. The justification of our use of infection as the criterion by which to assess forward surgery and chemotherapy, and the practical importance of pyogenic bacteria in a wound, are seen when the presence of infection is related to the results of suture.

Seven hundred and fifteen of the wounds were sutured. Wound repair was the work of a group of surgeons (specialists, graded surgeons, and trainees), so that the results were representative of what can be achieved in the large-scale suture of wounds when penicillin is used as a routine. Seventy-five per cent. of wounds achieved the first grade of union (i.e., above 85% union); of the remaining 25% one-half obtained an intermediate grade of healing (70 to 85% union) and one-half were relative failures.

When the results were arranged according to the presence or absence of infection in the wounds at the time of operation it was found that the presence of pyogenic organisms had an adverse influence. This was seen most clearly when the clean and dirty wounds were considered separately.

Of 614 clean wounds 424 were free from pyogenic organisms, and 85% of these obtained Grade I union; 190 wounds were infected, and only 62% of these attained the first grade. Of 101 dirty wounds 52 were free from pyogenic bacteria, and 80% of these obtained Grade I healing—that is, almost the same degree of success was obtained as in the suture of uninfected clean wounds. The 49 infected dirty wounds did not do well, only 37% reaching the first grade. The full results are given in the Appendix (Tables A and B).

Thus the results of suture were related less to the appearance of the wound than to the presence of pyogenic bacteria. This does not mean that a bacteriological examination of the wound should be carried out before suture is performed. On the contrary, the surgeon is encouraged to suture wounds (in the presence of penicillin) whether they appear clean or dirty. The significance of these findings is to confirm the importance of pyogenic bacteria in the wound at the time of arrival at the base hospital, and thereby to emphasize the value of the control of infection by early operation at the C.C.S., by the use of penicillin–sulphathiazole powder as a bacteriostatic at the forward operation, and by avoidance of dressing of the wound between forward and rear surgeons.

Influence of Resistant Strains of Staph. pyogenes aureus on Suture

All strains of *Staph. pyogenes aureus* were examined for the property of resistance to penicillin. Of the strains 20% were resistant to the concentration of penicillin that is produced by parenteral therapy (1/10 unit per c.cm.), but only one-half of these strains grew in 10 units of penicillin per c.cm., and few grew in broth containing 50 units per c.cm. Thus while 20% of strains of *Staph. pyogenes aureus* could fully resist the concentration of penicillin that obtains in parenteral therapy, many of these strains could be influenced by the increased concentrations that local therapy might provide.

It will be recalled that of the 614 clean wounds 190 were infected. Among these 190 strains of *Staph. pyogenes aureus* 33 were "resistant." Suture of the 33 wounds, accompanied by the local use of penicillin, was followed by the same standard of union as was the suture of clean wounds infected with "sensitive" strains.

The high concentration of penicillin that is obtained by local penicillin therapy has been shown to be of advantage in some situations—e.g., in the pleural cavity (d'Abreu *et al.*, 1944) and in compound fractures (Bentley *et al.*, 1944). These present results of suture indicate that it is also of value in dealing with strains of staphylococci possessing some degree of resistance to the drug.

Summary

In an investigation of 1,000 wounds during the battle for the Gothic Line the organism of initial sepsis was found to be *Staph. pyogenes aureus*. *Str. pyogenes* (haemolytic streptococcus) was rarely found.

The incidence of infection in wounds before operation at the C.C.S. was about 51%.

In wounds undisturbed during transit, and treated at the C.C.S. by operation alone, 49% were infected and 23% were septic; by operation and sulphanilamide powder, 43% and 11%; by operation and penicillin–sulphathiazole powder, 25% and 7%, when examined in the base hospital 5 to 10 days later. Thus operation alone did not completely remove infection from a recent wound. Its effect was to leave the wound in the best possible condition for dealing with the infection that remained. Sulphanilamide applied locally had a bacteriostatic effect; for although the infecting bacteria persisted, their activity was depressed, so that the incidence of sepsis was reduced. Penicillin–sulphathiazole powder similarly applied was more effective; for its use was followed by the destruction of the infecting cocci in about one-half of the infected wounds, with an equally low incidence of sepsis.

Wounds operated upon at the C.C.S. in under 12 hours had a lower incidence of infection than those operated upon between 12 and 24 hours, in all the chemotherapy groups. The length of time between wounding and arrival at the base hospital was found to make no significant difference in the infection rate.

Wounds that had been re-dressed between C.C.S. and base hospital had a higher incidence of infection than had those that had not been disturbed.

The importance of control of infection by operation and chemotherapy at the C.C.S. is illustrated by the results of suture. The presence of pyogenic organisms in the wound at the time suture was performed had an adverse influence on the result obtained. Of wounds uninfected with these organisms 80 to 85% obtained Grade I union, whether appearing clean or dirty; whereas wounds that were infected, even if appearing clean, showed a lower rate of success.

The presence in wounds of staphylococci possessing some measure of resistance to penicillin did not influence the results of suture when penicillin was employed locally in the wound.

APPENDIX

Table A.—*Results of Suture of 614 Clean Wounds in Relation to Infection*

Condition	Total No.	Degree of Success of Suture		
		No. Achieving Grade I Union	No. Achieving Grade II Union	No. Achieving Grade III Union
Infected ..	190	118 (62%)	37 (20%)	35 (18%)
Non-infected ..	424	362 (85%)	33 (8%)	29 (7%)

Table B.—*Results of Suture of 101 Dirty Wounds in Relation to Infection*

Condition	Total No.	Degree of Success of Suture		
		No. Achieving Grade I Union	No. Achieving Grade II Union	No. Achieving Grade III Union
Infected ..	52	19 (37%)	9 (17%)	24 (46%)
Non-infected ..	49	39 (80%)	9 (18%)	1 (2%)

Grade I union = 85% union or better. Grade II union = 70 to 85% union. Grade III union = Under 70% union.

The data on which this paper is based are taken from a report to the Director of Pathology, War Office, by Thomson and Bentley (1944). We are grateful to Major-Gen. L. T. Poole, D.S.O., *M.C.*, for permission to publish from the War Office report.

BLAST INJURY TO THE LUNGS

CLINICAL AND RADIOLOGICAL FINDINGS AND THEIR RELATION TO CERTAIN SYMPTOMS

BY

G. R. FEARNLEY, M.D., M.R.C.P.

(From a War Hospital)

The effects of explosive blast on the lungs have been studied by Zuckerman (1940) in animals, and clinical and post-mortem findings during the present war, recorded by a number of observers, correspond in the main with those found experimentally. The lesion as it affects the lungs is haemorrhage due to capillary rupture, or possibly diapedesis (Hadfield, 1940–1). According to their severity, Zuckerman has classified the lesions as: (1) a few small haemorrhages on surfaces of lungs; (2) patchy haemorrhages throughout the lungs; (3) complete hepatization of the lungs by haemorrhages. His explanation that the lesions are produced by the wave of positive pressure acting directly on the chest wall would appear to be generally accepted and is convincingly supported by his work. The general clinical picture is definite enough in the groups of cases reported, but both individual symptoms, such as haemoptysis, and radiological evidence of blast injury have a varied incidence.

The Cases

Among the large number of chest injuries, penetrating and non-penetrating, admitted to this hospital 21 appeared to have been caused by blast, and were unaccompanied by additional trauma. No case has been included in which fractured ribs might account for damage to the lung or pleura or in which there was a history of burial by debris together with bruising of the chest wall. A certain amount of selection was inevitable, as only patients fit to travel reached this hospital, the interval between injury and arrival being on the whole proportionate to the severity of the condition. Only one of the cases was seen here earlier than three days after wounding; the majority arrived three to five days and several as long as 10 to 14 days after. It was thus possible to observe cases at different intervals after injury and watch their progress for a few days before sending them on to base hospitals.

The explosive sources were hand-grenades, mortar bombs, land mines, aerial bombs, and in two cases flying bombs.

Although unconsciousness occurred at the time of injury in the majority, the accounts of the positions of the patients in relation to the explosions, the type of bomb, and in many cases the distance from the explosion were surprisingly detailed. With few exceptions the blast seemed to have been sustained chiefly by the chest, and, conversely, cases of abdominal blast —not included in this series—were noticeably free from pulmonary symptoms.

Table showing Inverse Relation of Haemoptysis to Incidence of Massive Haemorrhage as revealed by Radiographs

Case	Explosive Source; Position	Time Unconscious	Pain	Cough	Haemoptysis	Signs in Chest	*X*-Ray Findings in Chest
1	Aerial bomb; 50 yards Prone	0	21 days; retrosternal	21 days	1st–12th days; intermittent	Nil 2nd, 5th, 7th–21st days	Nil 2nd, 6th, 12th, 15th days
2	Mortar bomb; 3 feet Facing	8 hours	5 days retrosternal; 10 days upper abdom.	11 days; blood	1st–11th days; intermittent	General rhonchi 1st–3rd days	Nil 1st, 2nd, 3rd, 9th, 10th, 11th days
3	Aerial bomb; 30 yards Facing	0	5 days; retrosternal	8 days mucoid sputum	3rd–10th days; intermittent	Cyanosis, hyperexpansion and general rhonchi 1st day; nil 2nd day or later	Nil 2nd, 6th, 9th days
4	Land mine; 4 yards Left side	5 mins.	3 days; right chest	5 days; mucoid sputum	4th–9th days; daily	Nil 1st, 3rd, 5th, 9th days	Nil 4th, 7th days
5	Land mine; "close" Supine	0	6 days retrosternal and back	5 days; bloody sputum	1st–5th days	Nil 1st, 2nd, 4th, 7th days	Nil 6th, 9th days
6	Mortar bomb; 5 yards Facing	5 hours	10 days; whole chest	5 days; blood	1st–5th days; daily	Generalized rhonchi 1st day; nil 3rd, 5th, 7th days	Nil 1st, 3rd, 8th days
7	Mortar bomb ? ?	3 hours	7 days; whole chest, left arm	3 days; blood	1st–3rd days; daily	Generalized rhonchi 1st day; nil 3rd, 5th, 7th days	Nil 1st, 3rd, 5th days
8	Mortar bomb; 10 yards ?	5 hours	3 days; upper abdom., left back	3 days; dry	3rd day	Nil 1st, 4th, 6th days	Nil 4th day
9	Grenade; 3 yards Right side	Few mins.	5 days; right chest	3 days; frothy sputum	1st day	Nil 4th, 6th days	Nil 4th day
10	Grenade; contact Left side	"Short time"	7 days; left chest and arm	7 days; mucoid sputum	1st–4th days	Generalized rhonchi 1st day	Nil 1st day; right interlobar fluid 3rd day
11	Mortar bomb ? Right side	0	8 days; left chest	1 day; bloody sputum	1st day for 6 hours	Nil 1st, 4th days	Increased density left lower zone 4th day
12	Aerial bomb; 25 yards Prone	0	4 days; left chest	5 days; mucoid sputum	1st day	Cyanosis, rapid breathing, no signs in chest, 1st day; nil 4th, 6th, 8th days	Opacities both midzones 4th day; nil 8th day
13	Aerial bomb ? Back to	Few mins.	2 days; retrosternal	1 day; blood	1st day	Generalized rhonchi 1st day; dullness and diminished B.S. at left base 5th day	Opacity left lower zone 5th day; opacity clearing 8th day
14	Aerial bomb ? ?	? hours	2 days; right chest	1 day	1st day	Dullness and diminished B.S. at right base 1st day; diminished B.S. and creps. at right base 13th day	Heavy opacity right lower zone, small opacity left midzone, 3rd day; clearing on right, left side clear, on 6th day; nil 12th day
15	Flying bomb ? ?	0	10 days; whole chest	Chronic bronchitic	0	Left haemothorax 3rd day; aspirated	Left haemothorax; clear by 24th day
16	Shell; 20 yards Back to	0	15 days; left chest	10 days; dry	1st day	Left haemothorax 2nd day; consolidation left base 12th day; clear 23rd day	Left haemothorax 2nd day; consolidation 13th day; pleural thickening 22nd day
17	Mortar bomb; close In trench	Few mins.	7 days; left chest	3 days; dry	0	Nil 3rd day; dullness left base 14th day	Nil 3rd day; opacity left base 14th day; almost clear 17th day
18	Flying bomb; 20 yards Back to	0	4 days; retrosternal and back	3 days; dry	0	Nil 1st and 2nd days; dullness, diminished B.S., and creps. right base 3rd day; nil 4th day	Nil 2nd and 4th days
19	Mortar bomb; 3 yards Left side	3 hours	14 days; retrosternal, left chest	0	0	Nil 1st day; dullness and diminished B.S. left base 3rd day; nil 8th day	Opacity left base 3rd day; cleared 8th day
20	Aerial bomb ? Prone	6 hours	14 days; left chest, back, upper abdom.	0	0	Generalized rhonchi 1st day; consolidation right base 4th day; resolving consolidation left base 14th day	Bilateral midzone opacities right > left. 4th day; opacity left base 14th day
21	Mortar bomb; 3 yards Crouching	0	10 days; upper back	0	0	Cyanosis, scattered creps. both lungs 1st and 2nd days; dullness and diminished B.S. at left base 9th day	Increased density left lower zone 9th day; nil 11th day

Symptoms

The attitude of mind of these patients was strikingly calm, contrasted with the anxiety and over-reaction shown by many of those with penetrating wounds; perhaps they took heart of grace from their immunity to the repeated and sometimes fruitless needling suffered by their fellows. Over half the patients (12) were unconscious for a few minutes to several hours after injury. No abnormal physical signs in the central nervous system were recorded, and in no case was lumbar puncture performed. None of these patients complained of subsequent headache.

Dyspnoea.—This symptom was experienced by all, lasting from a few hours to several days after injury, but was not persistent. Painful respiration, however, in patients with muscular tenderness led to discomfort in transport and lasted from ten days to three weeks. "Tightness" and a "blown-up feeling" were expressions unhumorously used by many patients to describe their sensations after being exposed to blast, and in these cases rapid wheezing respirations, coughing of frothy blood-stained sputum, and sometimes cyanosis were recorded.

Pain was a constant feature, but its duration varied. Two types occurred, sometimes separately, sometimes together: (1) retrosternal pain, constant or intermittent, the latter often relieved by coughing up mucus or blood; (2) muscular pain, accompanied by tenderness, occurring most commonly in the intercostal muscles and occasionally in the upper abdomen and muscle masses of the back. In some cases the pain was severe, with extreme tenderness a week or more after injury, limiting respiratory movement. Where the blast had been unilateral the upper-arm muscles on the injured side were apt to be affected.

Cough.—All but two cases suffered from cough; both these patients showed radiological evidence of pulmonary haemorrhage but emphatically denied cough as a symptom, nor did it occur while they were in this hospital. Coughing of frothy and sometimes blood-stained sputum for several hours after injury was common. After this the cough might become dry, or mucoid sputum would be expectorated for a few days. This symptom seemed to bear no relation to the intensity of radiological change. *Haemoptysis* occurred in 15 cases, and is discussed below.

Other Symptoms.—Epistaxis occurred during the first 24 hours after injury in Case 7. The tympanic membranes were not inspected as a routine (the ear drums were examined only in Cases 1, 5, 11, 12, 16, and 17), but the only patient to complain of deafness was No. 11, who had a perforation of the right drum.

Physical Signs

Blood-pressure readings and pulse, temperature and respiration rates were recorded infrequently before admission to this hospital, but, with the exception of Case 18, the charts showed nothing remarkable after admission. This patient, whose temperature was 99°, pulse 88, and respiration rate 20 on admission, three hours after being blasted by a flying bomb, had a temperature of 104°, a pulse of 110, and a respiration rate of 36 fifty-six hours after admission. Examination then showed undoubted dullness and diminished breath-sounds at the right base. Radiographs taken 24 hours before and 36 hours after this examination showed no abnormality, and agreed with an absence of abnormal physical signs at these times; it was thought that he had had a temporary partial collapse of the right lower lobe. He continued to have a low pyrexia—99 to 100°—for eight days after this, but the tachycardia and respirations subsided within 48 hours.

Generalized rhonchi were found commonly in those cases examined soon after injury, but lasted only for a few days. Cases radiologically clear on arrival here showed either nothing abnormal on physical examination (apart from muscular tenderness and limited respiratory excursions due to the pain) or the occasional rhonchus found in a large number of healthy chests. Dullness, diminished breath sounds, and decreased fremitus were present in those patients with heavy radiological shadows, clearing *pari passu* with the radiographs. Cases 15 and 16 had signs of effusion, and aspiration produced bloody fluid. Both haemothoraces cleared up with repeated aspiration.

X-Ray Findings

Ten of the cases showed no detectable abnormality in chest films taken within a few days of injury. Five of these were *x*-rayed within 36 hours of the incident, and in all but two patients a further film or films were taken later. Eleven cases showed radiological abnormalities in the chest at some time, and of these Cases 10 and 17, whose first chest films revealed nothing abnormal, developed respectively the appearance of interlobar fluid and a dense opacity in the left lower zone. Case 10, in which by the third day there was a shadow indicative of fluid in the right middle fissure, was not aspirated, but it seems likely that serous fluid or blood may have taken this time to accumulate. Case 17 had a clear film two days after injury, but a film taken on the fourteenth day showed a heavy opacity in the left lower zone, clearing remarkably quickly by the seventeenth day. Unless atypical pneumonia is postulated—and there was no corroboration by pyrexia or cough—this finding is difficult to explain, as even if haemorrhage into the lung is progressive the onset in this patient seems to have been very long-delayed. There was nothing specific about the shadows of the radiologically positive cases; they were unilateral in some instances, bilateral in others, and varied from increased density to the appearance of massive consolidation. All opacities were in the middle and/or lower zones, situated for the most part centrally. The shadows were confluent and not patchy. Phrenico-costal sinus pneumonia (Osborn, 1941) was not seen. Thomas (1941) has described hyperexpansion of the chest, but this was not a noticeable feature in the chest films of my cases. There seemed to be little correlation between the severity of the symptoms and the amount of damage as revealed by *x*-ray films. Tunbridge and Wilson (1943) are convinced that the extent of the haemorrhage is not always commensurate with the severity of the exposure to blast.

Haemoptysis

Haemoptysis has been an inconstant symptom of reported cases. None of those described by Dean, Thomas, and Allison (1940) coughed blood, though Hadfield (1941) found that haemoptysis commonly occurred an hour or so after injury. Livingstone (1940–1) reported occasional blood-stained sputum with loose cough. O'Reilly and Gloyne (1941) did not find haemoptysis to be persistent. It might be expected that haemoptysis would be related to the degree of haemorrhage—i.e., would occur in those cases showing massive *x*-ray shadows. This relation, however, was not found. Fifteen cases in all had haemoptysis at one time or another; of these, nine showed no radiological changes after injury. Of the 12 radiologically positive patients only six had haemoptysis, and, furthermore, only Case 10 coughed blood or bloody sputum for more than one day. Contrasted with these, six of the radiologically negative cases had haemoptysis for 12, 11, 8, 6, 5, and 5 days respectively. The accompanying Table, in which cases are arranged in order of persistence of haemoptysis, shows the inverse relation of this symptom to the incidence of massive haemorrhage as revealed by *x* rays. Those whose haemoptysis was of brief duration coughed bloody froth after injury, whereas those with prolonged haemoptysis brought up pure blood, sometimes with clots, intermittently. The following case is illustrative:

Case 2

On Aug. 8, 1944, a mortar shell fell on this patient's gun. He was facing the explosion and was unconscious for eight hours. He then had difficulty in breathing, and lower retrosternal and upper abdominal pain; he was also coughing blood-stained froth. On examination generalized rhonchi were heard in both lungs. Radiologically the chest was clear.

Aug. 10.—Still having frequent haemoptyses (pure blood). Generalized rhonchi in both lungs. *X*-ray films of chest clear. He continued to cough blood once or twice a day until Aug. 15. Before each haemoptysis he had pain under the right ribs anteriorly.

Aug. 15.—No haemoptysis.

Aug. 16.—Haemoptysis began at 5 a.m.; fairly copious, with small clots. A few sonorous rhonchi in both lungs. Radiographs of chest showed slight frosting of periphery of left mid-zone (indefinite). Evening temperature 99°. Pulse and respirations normal.

Aug. 17.—No cough or haemoptysis. No abnormal signs. Radiographs of chest clear.

Aug. 18.—Haemoptysis; coughing small clots from 11 a.m. to 4 p.m. Temperature, pulse, respirations normal. No abnormal signs in chest. Posterior rhinoscopy showed nothing abnormal. Chest films clear.

Aug. 23.—No further haemoptysis since Aug. 18.

Cases 1 and 3 pursued a similar course. A civilian (not included in this series) injured by an aerial bomb early this year had haemoptysis for three weeks with repeated clear radiographs.

Considering the discrepancy between the degree of haemorrhage revealed by *x* rays and haemoptysis as a symptom, it seems possible that the source of bleeding in those patients with clear films may be bronchial. It was not desirable to submit these patients to bronchoscopy, but further investigation into the source of haemorrhage in such cases would be instructive. Hadfield (1940–1) mentions a patient showing no external signs of injury who recovered from his more urgent respiratory symptoms in the course of a few days, but had four attacks of haemoptysis during the next seven weeks. He believes that the major clinical manifestations are more probably due to capillary dilatation than to actual bleeding into the lung, which may be a consequence of capillary dilatation, and considers that one result of the detonation of high explosives is that the lung is left in such a condition that it is liable to bleed intermittently for a considerable time after the injury. His case is similar to the three cases in this series in which there was prolonged haemoptysis, but if his explanation is correct it should follow that those patients who show signs and radiological evidence of extensive diapedesis or capillary rupture would be the most likely to have prolonged haemoptysis.

Unilateral Lesions

Zuckerman (1940) has shown that rabbits exposed to lateral blast, the opposite chest being protected by cotton-wool, suffer more severe damage to the lung on the exposed uncovered side and less severe damage to the contralateral lung. Clinical reports of cases, so far as I am aware, have not stressed unilateral lesions; these were not likely to occur as most of the reported cases have been due to injury by aerial-bomb blast. Many of my cases were blasted by less powerful sources—e.g., mortar bombs or grenades—and some appeared to have been affected by the close-range detonation on one side only. Eight patients had unilateral abnormalities as shown by radiograph, although in some of these cases minimal lesions on the other side may have cleared by the time the films were taken. Five patients said that they were sideways-on to the explosions, and of these, three gave unilateral shadows, the remaining two being radiologically negative. It seems reasonable to assume that, whatever the effect on the lungs, pain and tenderness of the chest muscles should occur on the side facing the explosion; but in two of the five cases (Nos. 4 and 11) pain with or without tenderness was experienced on the side opposite to that described as facing the explosion. The remaining three cases had pain on the exposed side, the following case presenting the anomaly of muscle tenderness limited to the arm and chest facing the detonation, with fluid appearing in the opposite interlobar fissure.

Case 10

This patient was injured on Aug. 8, 1944, by a hand-grenade which struck his left shoulder and exploded on or close to him. He was unconscious for a short time. On coming round he noticed soreness of the left chest and shoulder, and was coughing bloody sputum. On examination there was obvious dyspnoea, with generalized rhonchi in both lungs. Chest radiologically clear.

Aug. 9.—Still coughing blood-stained sputum.

Aug. 11.—Cough and haemoptysis. Pain in left chest and arm. Radiographs gave an appearance of a small effusion in the right middle fissure.

Aug. 12.—No change radiologically.

Aug. 15.—Some pain in left chest on breathing. Occasional cough; mucoid sputum; no haemoptysis. Examination disclosed tenderness in the left pectoralis major and shoulder-girdle muscles. No abnormal signs in lungs. Radiographs revealed only a small amount of fluid in the right middle fissure.

It would be unwise to draw conclusions from the case histories, for the evidence seems contradictory in two instances: No. 4, whose history was of a land mine exploding on his left side, the subsequent muscular pain and tenderness being on the right; and No. 11, who gave a history of a mortar bomb exploding on the right and presented the anomalous combination of a recent perforation of the right drum, the left being intact, and pain and tenderness of the left chest with radiological evidence of increased density of the left lower zone. Nor were any of the cases with unilateral histories and lesions comparable to Zuckerman's animals, for their chests were not protected on one side, and the blast may well have been received obliquely. Case 10, however, would seem to suggest the possibility of a contrecoup lesion if it were not for the difficulty of accepting such an effect on an organ so elastic as the lung.

Treatment

Treatment should be for the symptoms. Hadfield (1940–1) has emphasized the importance of adequate rest. None of these patients developed pneumonia—a not uncommon complication according to O'Reilly (1941); many of those showing evidence of massive pulmonary haemorrhage had been given up to 20 g. of a sulphonamide by the Army method of dosage of 5 tablets (2½ g.) twice a day during the first few days after injury, and this may well have prevented the complication. Physiotherapy would seem to be indicated for the muscular pain which is so prominent a symptom, followed by breathing exercises, but owing to pressure of more urgent work this could not always be carried out.

Summary

Twenty-one cases of blast injury to the lungs uncomplicated by other types of trauma are presented; the symptomatology, signs, and radiological findings are detailed. Haemoptysis as a persistent symptom is shown to bear no relation to the degree of pulmonary haemorrhage as manifested radiologically. Unilateral exposure to blast and the resulting lesions are found to have no constant relations; but in one case the possibility of contrecoup injury is mooted.

I would like to express my thanks to Dr. Geoffrey Doel for the *x*-raying of these patients and for his helpful co-operation at all times. I am also indebted to R.A.M.C. officers concerned for the early notes of the cases and in many instances for radiological investigations soon after injury.

AN OUTBREAK OF JAUNDICE WITH SIGNS IN THE NERVOUS SYSTEM

BY

E. A. J. BYRNE, M.D., M.R.C.P.
Major, R.A.M.C.

AND

G. F. TAYLOR, M.R.C.P.
Lieut.-Col., I.M.S.

In the steadily growing literature on infective hepatitis there is scant reference to lesions in the nervous system. In a series of 170 cases studied by Cameron (1943) the only neurological sign noted was a temporary paresis of accommodation in two cases. Newman (1942) refers to severe headache and to the occasional occurrence of paraesthesiae in the limbs. In none of his cases was the cerebrospinal fluid examined. Brain (1943) refers to one case in which unilateral convulsions and a hemiplegia, together with mild polyneuritic signs, preceded the onset of jaundice. Lescher (1944) gives three references to single cases of meningitis associated with infective hepatitis and describes two cases. A housewife aged 28 during an epidemic of infective hepatitis developed signs of a generalized polyneuritis which was followed one week later by jaundice; recovery was complete. In the second case an R.A.S.C. driver suddenly developed a left hemiplegia two months after an attack of epidemic hepatitis, from which he had made a complete recovery; there seems little justification for associating these two illnesses.

History of the Outbreak

The cases which are the subject of this note show the association of lesions of the nervous system with jaundice in several individuals living in close proximity. In Sept., 1943, a casualty clearing station in the Arakan, on the Burma front, was receiving a few cases of infective hepatitis each week, differing in no way from the usual type. Within two days 5 cases of jaundice with unusual neurological symptoms and signs were admitted. Four of these patients were from one British regiment and the fifth was an officer who had been working with this unit.

The history and clinical findings in four of the cases were very similar. The onset of the illness was sudden, occurring while the battalion was marching down to relieve another in the front line. All four men went sick within 48 hours of each other, with severe headache, dizziness, and a rise in temperature to about 104° F. Pain behind the eyes and generalized body pains, worse in the neck and in the back, were constant features. A "pins and needles" or tingling sensation rapidly developed in the arms and legs, with loss of muscular power, particularly in the lower limbs. Some degree of dimness of vision was noticed by each of the patients.

The fever lasted two or three days. A moderate jaundice developed on about the fourth day. When examined at the C.C.S. 10 days after the onset the following signs were noted. All four men were mildly jaundiced and bile was present in the urine. The liver was tender and enlarged and the spleen was palpable in all cases. The total and differential white counts were normal. The men complained of dizziness, dimness of vision, unsteadiness, and weakness of the limbs. On attempting to walk they staggered. During the first few days of the illness Kernig's sign had been reported as positive; a slight degree of neck rigidity still remained. The fundi were normal apart from a fullness of the veins in three cases. The remaining cranial nerves were normal. There was no loss of power, and no incoordination was present in the upper limbs. The arm and abdominal reflexes were normal. The lower limbs showed varying degrees of muscular weakness. The knee-jerks were diminished, though unequally on the two sides; in one case the right knee-jerk was absent. The ankle-jerks were absent. The plantar responses were flexor, except in one case which showed equivocal responses. In two cases there was definite sensory loss in the thigh—in one case on the anterior surface and in the other along the posterior surface. The cerebrospinal fluid was abnormal in three of the cases. In two a clot developed 15 minutes after the fluid had been withdrawn. The protein content was increased in three cases. Cell counts were 23, 14, and 11 lymphocytes per c.mm. The Wassermann reaction was negative in all the fluids. Sera of these cases gave negative results on agglutination with the leptospira of Weil's disease.

The patients were evacuated to base hospitals, where three of them made a complete recovery within two months. The other two cases developed sequelae, as described below.

Case IV

C.S.M. J., aged 32, was seen by Major A. D. Leigh, R.A.M.C., neurologist, in Dec., 1943, three months after the onset. The following notes are extracted from his report. The patient complained of weakness and numbness in the legs. There was no jaundice and the liver was not palpable. The pupils and cranial nerves were normal. There was slight weakness of both hand-grips, with exaggerated reflexes in both limbs. Blunting to cotton-wool and pinprick was present on both hands. Power in both lower limbs was diminished, more particularly in the right leg. Muscle tone was increased in both legs and the gait was mildly spastic. The deep reflexes were much exaggerated, except the right ankle-jerk, which was diminished. The plantar responses were flexor. There was diminished sensation on the outer side of both thighs and over the dorsum of the feet, with absolute loss on the toes. The cerebrospinal fluid was normal. The patient was invalided to the U.K.

Case V

On Sept. 2, 1943, Capt. R., aged 33, complained of sore throat. On the 9th he had a rigor, which recurred despite quinine. On Sept. 14 he was admitted to an M.D.S., where his urine was noted to be dark in colour. The next day he complained of pains in the calves and thighs, and these were followed by loss of power from the hips downwards. On Sept. 17 there was a complete flaccid paraplegia, with anaesthesia below the groins. The patient complained of pain in the right arm, and on examination weakness of abduction was noted. There was no complaint of headache. On Sept. 19 he was admitted to a C.C.S.; he vomited several times that day. The next day he complained of headache, pain in the back, and blurring of vision with the onset of fever. There was difficulty in emptying the bladder. Jaundice was now present and the liver was enlarged and tender. The C.S.F. showed no increase in cells and the protein content was normal. The white cells numbered 9,000 per c.mm. Improvement was noted during the next few days, and on Oct. 2, on arrival at a field hospital, a considerable return of power and sensation had taken place in the left lower limb and, to a less degree, in the right. By the end of October no weakness of the right arm could be detected. The abdominal reflexes were normal. There was weakness of flexion of the right knee and of dorsiflexion of the right foot. Tone was increased in the right leg, particularly in the tendo Achillis. There was no appreciable wasting, and sensation was normal. The deep reflexes were exaggerated in the lower limbs, more particularly on the right side. There was unsustained right-sided ankle clonus, and the right plantar response was equivocal, while the left was flexor. By the middle of November power had further returned in the right leg, and the plantar response was now flexor. The patient was evacuated to the U.K.

Discussion

In four of the five cases described above an abrupt onset of fever, generalized pains, and signs of a mild meningitis were quickly followed by blurring of vision, weakness, and paraesthesiae in the lower limbs. In the fourth case pyramidal signs were subsequently noted, while in the fifth case the signs were predominantly those of a myelitis. Jaundice associated with enlargement of the liver and spleen appeared in all cases between the 4th and 6th days of the illness. Recovery was rapid and complete in three of them. In the remaining two a mild residual spastic paresis of the lower limbs, with in one case sensory loss peripherally, was still present several months later.

In considering the aetiology of the nervous signs in these cases acute poliomyelitis need be considered only in Case V. In Sept., 1943, only a single case of this disease was reported from this part of the Burma front. Furthermore, the myelitic form is distinctly rare, and it is unusual in such cases for recovery to be so rapid and the sequelae so mild. The normal cerebrospinal findings on the fifth day of the disease are also unusual. Since another case with mild myelitic signs occurred in the series, and since there were features in Case V rarely seen in acute poliomyelitis, this has been included.

The jaundice appeared to be of the usual infective type, especially since other cases from the same area were seen at that time. Assuming that these men suffered from infective jaundice, the question of neurotropism of the virus causing this condition must be considered. It is known that, experimentally, hepatotropic and neurotropic elements may coexist in viruses—e.g., yellow fever. On the other hand, taking into consideration the widespread distribution of infective hepatitis during the present world war and the extreme rarity of nervous complications, it is doubtful whether neurotropism of this virus can be accepted as the explanation in these cases. There remains the coincidental association of two diseases—a not uncommon event in the East. Encephalomyelitis, to which one case bears some resemblance, although not uncommon in peacetime, has been rare in the Army in India during the present war. We have not attempted to give a label to the neurological picture which these cases presented, but have indicated that meninges, spinal cord, and peripheral nerves were affected in varying degree.

Summary

A description is given of a small outbreak on the Burma front of a condition characterized by the association of jaundice with meningitis, peripheral neuritis, and, less constantly, myelitis.

The relationship of these conditions is briefly discussed.

Our thanks are due to Lieut.-Gen. W. Wilson, C.B., C.B.E., K.H.S., Director of Medical Services for India, for permission to publish this paper.

A SOCIAL STUDY OF HOSPITAL TREATMENT

BY

MALCOLM BROWN, D.Phil., M.R.C.P.

AND

FREDA C. CARLING, A.I.H.A.

(From the Nuffield Department of Clinical Medicine, Radcliffe Infirmary, Oxford)

Anyone with experience of modern hospital work knows that facilities for in-patient treatment are limited. It is therefore important that they should be used to the best advantage. Also, all those who deal with the sick know something of the impact on family life made by a serious illness, but few realize how it is borne. The present study is an attempt to assess the value and efficiency of the in-patient service of a general medical ward, and to discover how such a misfortune as a hospital illness is met by the patient.

The Patients Studied

Contact was made with all the patients who had been admitted to Collier Ward during a period of six months to see how far medical and social care had been adequate to meet their needs. The period between Aug. 1, 1941, and Jan. 31, 1942, was chosen because during that time one of us (M.B.) had been house-physician.

Collier Ward is divided into accommodation for 10 men and 11 women. It is attached to the Nuffield Department of Clinical Medicine, and although when it was opened in 1938 it was mainly intended for scientific investigation and research, by 1941 it was also taking its share in the clinical teaching of students and the general work of the hospital. The ward was staffed with a sister, seven nurses, and a house-physician, and the bed costs for the six months under review were £2,280.

The follow-up was begun in Feb., 1943, and a letter was sent to each of the 156 patients explaining the nature of the investigation and asking for their co-operation. Wherever possible the social worker (F. C. C.) then visited the patients, discussed the social implications of their illness, and arranged for them to come up to hospital for a medical examination. Seventy-two patients were visited in their own homes; 51 attended for medical examination; 31 lived too far away for a visit, but sent a letter and report from their own doctor. Only 6 remained untraced, and of these one was an evacuee, one a tramp, and two were from a near-by construction camp. Notes were made on the medical and social aspects of each case, and when the record was complete the questionary shown in Table I was filled in. All but two of the patients were delighted to hear from the hospital and know the staff were interested in their progress. They gave us unlimited co-operation.

Table I.—*Questionary used in the Follow-up and a Summary of the Answers*

Total number of cases		156
Dead	29	35
Untraced	6	
Number included in the questionary		121*
Medical	Yes	No
1. Is the patient still suffering from the disease which caused admission?	82	39
2. Is any present incapacity due only to a psychogenic overlap?	8	—
3. Did the follow-up visit end in a suggestion as to treatment or supervision?	31	90
4. (*a*) Is hospital treatment still necessary?	47	74
(*b*) If so, is it being given?	36	11
5. (*a*) Is other medical care still necessary?	35	86
(*b*) If so, is it being given?	29	6
6. Was patient seen by family doctor after discharge?	105	16
Social		
7. Is the patient now (*a*) employed in full-time work?	72	
(*b*) employed in part-time work?	30	
(*c*) totally incapacitated?	19	
8. Was the period of incapacity caused by the illness greater than three months?	98	52*
9. Was the stay in hospital longer than three weeks?	66	90†
10. Was the period of incapacity after discharge greater than three months?	73	48
11. Could this period (10) have been shortened by:		
(*a*) fuller co-operation of patient or family?	11	
(*b*) closer hospital supervision?	13	
(*c*) financial help?	5	
(*d*) occupational therapy?	6	
(*e*) other services?	19	
12. What were the sources of income during illness?		
(*a*) Wages paid by employer during illness	23	
(*b*) Insurance	64	
(*c*) Savings	32	
(*d*) Family funds	82	
(*e*) Public funds	16	
13. If the patient is not working full time now, what are the sources of income?		
(*a*) Pay from part-time work only	3	
(*b*) Insurance	6	
(*c*) Savings	6	
(*d*) Family	38	
(*e*) Public funds	2	
14. When the patient was a housewife, were reasonably adequate arrangements made for the care of the rest of the family:		
(*a*) during illness?	44	4
(*b*) during convalescence?	40	8
(*c*) at present time if still incapacitated?	21	3

* All the patients traced—i.e., 150—are included in the answer.

† All of the 156 patients are included in this answer.

All but 5 of the patients were civilians, drawn mainly from Oxford and the large rural area surrounding it. More than a third came from the country, and many of the Oxford townspeople have the outlook and attitude of country folk. Among those from the town 10% were evacuees from London. Eight per cent. of all patients were sent for diagnosis from considerable distances outside the usual area.

The housing conditions of patients, from both the urban and the rural areas, were good on the whole. The majority of our patients came from neat semi-detached houses with pleasant gardens and reasonable rents, or from country cottages with somewhat primitive sanitation but ideal positions and rents of a few shillings a week. There was little evidence of overcrowding or bad conditions.

Results of Treatment

Table I gives a summary of the medical and social status of the patients who were alive at the end of a year. Twenty-nine (19%) patients had died; 82 (55%) were still suffering from the disease which had caused admission, and another 8 (5%) were incapacitated because of psychogenic symptoms which remained after cure of their organic disease. Thirty-two (21%) patients had been admitted to other hospitals, 38 (25%) were still receiving out-patient care, and another 10 (7%) needed it. Almost as large a number required attention from their general practitioner. During six months the ward had cured only 39 (26%) of the patients admitted. For the majority of the patients the stay in hospital was merely an episode, sometimes a relatively brief episode, in a protracted period of disability and treatment.

A better impression is given if we show how many of the patients had returned to their occupations. Whereas only 39 (26%) could be considered cured in the strict medical sense, 72 (48%) had been able to return to full-time work, and 30 (20%) were doing part-time work. The group of patients with blood diseases did better than the others, while those with lung disease were much the worst.

For the purpose of this study the patients were divided into groups in three ways: (*a*) those under 45 years of age were compared with those of 45 and over; (*b*) those whose stay in hospital was 21 days or less were compared with those who were in hospital for longer periods*; and (*c*) those whose total period of incapacity was 3 months or less were compared with those who were incapacitated for more than 3 months. The results showed that patients under 45 years have a better chance of returning to full work than those who are older, and that the patients who stayed in hospital less than three weeks and those whose entire illness lasted less than three months had a better chance of recovery than the others. These facts are not surprising, but their implications are important.

Use of Available Bed Space

If the services of a well-equipped diagnostic ward are to be used to the best advantage the patients must be selected for suitability for admission, and they must be discharged as soon as practicable after the diagnosis has been made and such treatment as can be given in this type of ward has been completed. Little fault can be found with the choice of patients for admission. In the present state of hospital waiting lists it would be more appropriate to comment on the many suitable cases which fail to gain admission than on the few unsuitable ones which do. Of the patients who were traced, 99 had been admitted from the waiting list compiled in the out-patient department, and the remaining 51 were admitted as emergencies on the days when the ward was "on take."

Of those from the waiting list 73% had returned to work at the time of the investigation, whereas only 55% of the emergency admissions were working. This difference is probably due to the type of illness rather than the method of selection. In cases of emergency no request for the admission of a patient was refused, so that the decision was solely in the hands of the general practitioner. Only two of the patients admitted in this way did not require special investigation or treatment. One was a patient with disseminated sclerosis whose home conditions necessitated removal, and the other was a mild case of gastro-enteritis. Only one case was clearly hopeless—that of a woman with carcinomatosis—and here there was some possibility that radiotherapy would alleviate her pain. The record as a whole justifies the choices of the general practitioners. It is clear, then, that faulty selection of patients was not the cause of much waste of bed space.

If, however, we turn to the circumstances which governed the discharge of patients we find that there were many defects. There were 25 (16%) whose discharge had been delayed beyond the time they needed special treatment, and this involved the waste of 680 bed-days. The chief cause of delay was the lack of suitable institutions for the care of patients who needed only general nursing and possibly a special diet. To such a hospital some of our patients with peptic ulcer, for instance, could well have been sent for a month and then readmitted for a review of their condition, and the old people with bronchitis and asthma would have done as well in simpler surroundings. The patients of this type who had to be kept in the ward long after they required the special services it provided are listed in Table II. There was a smaller group

Table II.—*Causes of Undue Delay in Discharge from Hospital*

Absence of an institution providing nursing care and/or diet:	
Peptic ulcer	3 cases
Bronchitis and asthma	2 ,,
Chronic empyema	1 ,,
Chronic nephritis	1 case
Thyrotoxicosis; fibroids	1 ,,
Rheumatic fever	1 ,,
Meningitis	1 ,,
Undiagnosed cases	3 cases
Delay in supply of special services: radiotherapy, surgical specialists, etc.:	
Leukaemia and reticuloses	4 cases
Pulmonary Tb.	1 case
Carcinoma of lung	1 ,,
Renal stone	1 ,,
Essential hypertension	1 ,,
Delayed admission to another hospital:	
Psychoneuroses	2 cases
Tuberculous effusion	1 case
Diabetes; cataract	1 ,,
Estimated waste of bed-days: 680	

---

* Patients with diseases of the blood were not considered in the second analysis because they were usually studied for research purposes and were kept in hospital for observation longer than their condition demanded.

whose stay was unduly long because some special service was unavailable. It would be unreasonable to expect every facility to be available immediately it is required, and this has not been the standard. Rather, included in the group were those who had to wait two to five weeks for radiotherapy or who had to wait a fortnight or longer for the surgical specialist. A third group of cases was held up because it was impossible to arrange for their admission to a special hospital within a reasonable time. The war, with the crowding of hospitals which it caused in this area, was of course partly responsible for this, and in any event the group was small. All three of the causes of delayed discharge from hospital were beyond the control of those in change of the ward, but an analysis of this defect in the general organization of hospital services gives an indication of the importance of the problem. The time required to treat the 83 (55%) patients who were in hospital for three weeks or less was 879 days, and 58 (70%) of them returned to full work. If the beds had not been blocked by the 25 patients listed in Table II it might have been possible to treat another 65 acute cases and so to increase by more than 50% the number of patients who returned to full-time work. If this had been possible it might have meant an increase in the staff both in the ward and in the laboratories, etc., but this would have been justified in order to make the special ward facilities available to a greater number of patients.

After-care Facilities

The after-care arrangements which were made for these patients were often inadequate. During the time that these patients were in the ward many of the convalescent homes were closed on account of the war or reserved for special purposes, so that the type of convalescence which was provided is not a fair sample of what might be arranged for a similar group in peacetime. Convalescence lasting from a few days to 12 weeks was arranged for 22 patients. The average stay was 4 weeks. The majority were sent to small cottage hospitals near their homes so that they could be under the care of their own doctors, but sometimes it was impossible to arrange this. Although full particulars were sent with each case, the link between the hospital and the local doctor seems to have been deficient. Many patients were only too aware of the break in the continuity of treatment, and felt on the one hand that the specialists were no longer interested and on the other that the convalescent hospital did not understand their illness. Three of the patients took their own discharge before their convalescence was completed. The absence in the small hospital of many of the concomitants of specialized medicine probably played a part in this feeling. It was impossible to tell how far the criticisms were really justified, but even their presence was disturbing. They point to the necessity for careful explanation of the circumstances before the patient leaves the key hospital and a closer connexion between the doctors concerned than is provided by a case sheet.

There was unrest on other grounds. A great difference existed between the quality of the food in the Radcliffe Infirmary and that in the smaller hospitals. Good diet—and rightly so—takes a high place in the patient's idea of convalescence, but the food in these smaller hospitals was often much inferior to that supplied at the Radcliffe Infirmary, and special diets were sometimes unobtainable. Younger patients sometimes found themselves in a ward full of the very old. For instance, a boy recovering from rheumatic fever spent three months in a room with six beds, of which only one was occupied by a young man during part of his stay; all the other patients were old and infirm. At first he was unable to read because he was flat on his back, but no attempt was made to provide any diversion.

There was often resentment if it was necessary to send a patient to a hospital far from his home, even when the stay in the Radcliffe Infirmary, almost as far away from relatives, had led to no discontent. Several times one met the argument from members of the Hospital Contributory Scheme that as contributors they had a right to a bed in the Radcliffe Infirmary and should not be sent somewhere else. On the other hand one patient who went to a seaside convalescent home was most enthusiastic about the care he received and the value of a real change of surroundings. All of these are points of general application, some of which could be remedied by institutional reorganization, and some of which must be met and solved by a study of each case.

Six patients would probably have returned to work sooner if convalescent treatment had been provided. Two of these were women who refused to allow arrangements to be made because they were worried about their homes. Two men with peptic ulcer went home to unsatisfactory diets, partly the result of their poverty. A woman with a breast-fed baby was a contingency for which no provision could be made at short notice. Another woman, who was referred to the psychiatric clinic and needed a period of rehabilitation, returned home to be nursed by her mother, an over-possessive person partly responsible for her daughter's psychoneurosis. Thus the shortage of beds for convalescents was the cause of incomplete treatment in four of these cases, and lack of provision in the home when the mother was ill was the cause in the other two.

Time and facilities for closer follow-up, and financial help, would have aided the recovery of another sizeable group of patients (Table I, Question 11). For instance, some who did not follow instructions after discharge might have been persuaded to do so. In three cases poverty made proper care impossible. At least 12 patients would have been benefited if occupational therapy had been provided during their incapacity. In 6 of them the return to work might have been accelerated; others might have had their interest aroused in the ward, and the work could have been carried on at home to avert boredom. For some this would have been an activity which would have continued through years of incapacity.

Provision for housewives during illness and convalescence is a special problem. Several would have been helped by such services as residential nurseries for their children, home helps, and other forms of social care. Many expressed the wish that there was an insurance scheme for them. The husband's weekly wages often do not go far when he or a neighbour does the shopping, and the housewife in hospital worries about the family budget. All those who belonged to the District Nursing Association spoke most highly of the service. There seems no reason why a Home Help Service for the convalescent and semi-invalid housewife should not be run on similar lines.

Social Adjustments during Illness

When studying the social effect of illness involving admission to hospital it is necessary to know something of the make-up and background of the group of patients. Their occupations will give some indication of this. Of the 156 patients admitted, 91 were gainfully occupied; 28 of these were women employed in domestic, professional, clerical, and factory work. The remaining 65 patients in the series were housewives or children. The group of 91 workers was divided as follows:

Domestic workers	11
Labourers	14
Clerks and shop assistants	15
Farm workers and gardeners	14
Skilled workers	21
Professional workers	11
H.M. Forces	5

Omitting the 5 Service cases, 66% were urban workers and 34% rural workers. Twenty of these patients died. Nineteen of them were men, of whom 10 were urban workers, 8 rural workers, and 1 in H.M. Forces.

On the whole the patients came from a stable population and, apart from those who had come to Oxford on account of the war, most of them belonged to families who had lived in the neighbourhood for several generations. Family ties appeared to be strong, and many patients relied upon their relatives to help them during their illness. The expense of hospital treatment had largely been provided for by membership of a hospital contributory scheme. Seventy per cent. belonged to the Radcliffe and Associated Hospitals Contributory Scheme or a reciprocal scheme, and while the funds obtained in this way did not completely cover the cost of treatment, contributors must be considered to have borne a major part of the expense. Only 8 patients were unable to pay anything or were on public assistance.

The means of meeting the expenses of medical treatment and the running of the home are listed in Table I, Question 12. Only 5 patients applied for public assistance; another 11 were eligible for special grants from local authorities. Other State funds, such as the N.H.I. benefits, were of course obtained in the usual way, although by themselves they were quite inadequate to meet the needs of a long illness. Only 32 had enough savings to tide them over the crisis, and in a great many instances other members of the family rallied round during the illness. This illustrates the strength of family ties, and it is significant that of the 5 who found it necessary to apply for public assistance, 4 were single persons with no family backing.

For those patients with a high standard of living the inadequacy of benefit is pronounced in spite of sick clubs and savings. But the most striking examples of the inadequacy of the benefit are the cases where the man with a young family is sick. One of our patients suffering from a peptic ulcer, who had a young child and whose wife was pregnant, had his benefit supplemented by the Public Assistance Committee. He felt ashamed of having to apply for relief, and although he felt ill, dared not go to a doctor for fear of being put off work. This abhorrence of obtaining relief through the Poor Law is deeply ingrained, and adequate provision should be made through insurance for the whole family when the bread-winner has the misfortune to be ill. Employers, particularly the farmers, were generous to their workers during their illnesses, and 23 were given their full wages throughout the entire period. Many others had generous allowances.

Examination of the sources of income for the 49 (40%) patients who were not working full time (Table I, Question 13) showed that the incapacitated also relied mainly on family support. There were only 2 (4%) patients on public assistance, but only 10 (20%) had adequate pensions, savings, or sufficient pay from their part-time work to maintain themselves. The great majority (76%) relied on assistance from relatives. One of those on public assistance—a young woman who had been ill since contracting infantile paralysis in childhood—had never been taught a craft, and although she could have done some dressmaking and had a sewing-machine, regulations would not allow her to supplement her allowance by earning, and so she preferred to leave her machine idle and be sure of her weekly grant.

Value of a Long-term Follow-up of this Type

The review of this group of patients led to some addition to treatment in 31 (25%) cases (Table I). There were a few instances where a new development in the patient's condition required direction. In others the treatment prescribed on discharge needed to be started again. Each patient was questioned to find the effectiveness of liaison with the general practitioner (Table I, Question 6). On the whole it was satisfactory, and the majority of our patients had been seen by their family doctor soon after discharge. Despite this a few major aberrations were discovered. For instance, one patient with auricular fibrillation who had been sent out on digitalis therapy was dismissed by her doctor in a few weeks, and was found to be so ill when she visited the hospital that her name was put down for readmission. Another woman, who had left Oxford —a case of pernicious anaemia—had not had an injection of liver extract for more than a year. Altogether, readmission to hospital was recommended in 3 cases, out-patient treatment in 9, a surgical consultation in 2, and 6 were referred to their own doctors.

There were equal opportunities, some of which have already been mentioned, to improve the social management of a number of cases. Because of ignorance of the arrangements some patients had not received benefits to which they were entitled—statutory benefits as well as those from voluntary agencies. Several men had not understood national health insurance, and gave up when they got muddled in the procedure of application. There was some acute need at the end of a year in 15 (12%) cases, and the steps taken to meet it included such things as the provision of dentures, the arrangement of meals for a child, reference to a mental welfare worker, and the direction to training centres of several patients who were fit but not employed.

When this group of patients was in the ward the Almoner's Department consisted of 3 trained almoners, 2 senior clerical assistants, and a shorthand-typist, and it had to deal with a 500-bed hospital as well as out-patient clinics. Understaffed as it was, it gave help to 25 patients covered by this study. Looking back, it was clear that 36 more patients needed help which only the hospital could provide, and another 23 might have been referred to other agencies for assistance. Thus 70% of the patients required supervision if full use was to be made of existing social agencies and if recovery was to be as rapid and comfortable as possible.*

For purposes of clinical research it is probable that follow-up studies are of little value except when specific conditions are the subject of special investigation. This fact has perhaps made the hospital physician less conscious than he should be of the importance of the follow-up as a part of the patient's treatment. Our study has shown that only a small proportion of patients are completely and speedily cured as a result of admission to a medical ward. For the majority of them it constitutes a short episode in a long period of disability, and unless in-patient treatment and after-treatment are closely integrated, much of the benefit of the stay in hospital may be lost. Some of the defects we have noted would be remedied by an improved regional hospital organization in which the key hospital occupied a central position and the auxiliary and special hospitals, sanatoria, and convalescent homes took their places as equally important parts of the whole plan. The greater part of the patient's difficulties, however, would still remain.

It is our conclusion that the social problems which face patients who are admitted to hospital are so numerous and important that they demand attention. They are closely related to treatment, and unless patients are given adequate social care during the period of rehabilitation they may find it difficult once again to take their place in society. This care should be available at each stage of recovery until the optimum adjustment has been reached. It will involve liaison with many social agencies. A study of the type we have presented does not in any way take the place of this continuous care, but it serves several useful purposes. First, it draws attention to defects in hospital organization; secondly, it is an opportunity to discover patients' attitudes to the hospital service; thirdly, it reviews the correlation between the services inside and outside the hospital; fourthly, it enables individual patients to be helped where medical or social care has been inadequate; lastly, it indicates changes which can be made to benefit future patients.

Summary

150 consecutive patients who had been treated in a general medical ward in a teaching hospital were followed up 12 to 18 months later.

Only 26% had been cured, though 48% had returned to full-time work and 20% were doing part-time work.

Age over 45 and an illness of over three months' duration are bad prognostic signs.

Delay in discharge of patients from hospital because of the absence of suitable institutions for the care of long-term sickness is an important cause of wastage of bed space.

Arrangements for convalescent treatment and rehabilitation were defective, and, on the whole, cottage hospitals proved unsuitable for convalescence.

Contributory schemes and assistance by relatives are important factors in taking the financial strain of illness in this area.

In retrospect it is clear that 70% of the patients required supervision after discharge if full use was to be made of existing social agencies and if recovery was to be as rapid and comfortable as possible. This type of supervision could be given by an almoner, with reference of selected cases to medical officers.

Grateful acknowledgment is made to Mr. A. G. Sanctuary, administrator, Radcliffe Infirmary, for permission to make this investigation, and to Miss Helen Rees, chief almoner, and Prof. L. J. Witts for their interest and help.

---

* Since this study the Almoner's Department in the hospital has been augmented by 1 part-time and 4 full-time almoners and additional clerical assistance. An almoner is now attached as social worker to the Nuffield Department of Clinical Medicine. A voluntary worker skilled in handicrafts also visits the ward and guides those patients who are able to benefit by simple occupational therapy. It is hoped to carry out another follow-up of this type at a later date to discover what has been the effect of these changes.

PULMONARY ACARIASIS IN MONKEYS

BY

L. J. DAVIS, M.D., F.R.C.P.Ed.

Lecturer, Department of Medicine, University of Edinburgh

In view of the attention recently directed to the possible significance of mites in the causation of certain pulmonary disorders such as asthma, bronchitis, and "eosinophil lung" in the Tropics (Soysa and Jayawardena, 1945; Carter, Wedd, and D'Abrera, 1944), it may be of interest to refer to earlier observations on pulmonary acariasis in monkeys, since this condition is probably known to but few medical men.

Some Observations on the Condition

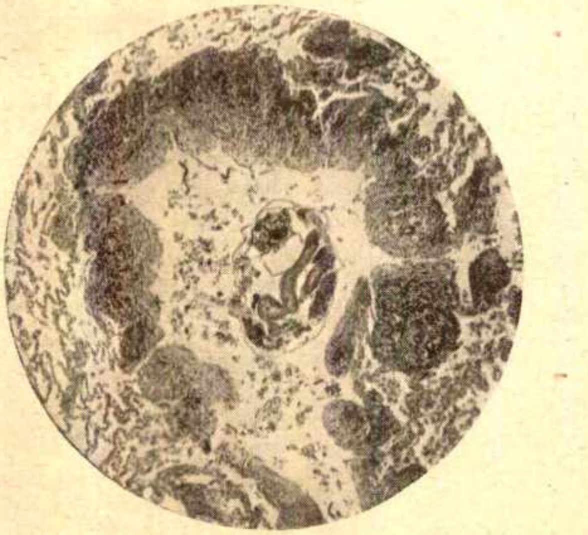
I first became aware of the phenomenon in 1933. When dissecting a *Macacus* monkey in Hong Kong I noticed small nodules scattered through the lungs. To the naked eye they resembled early tuberculous foci, although no other manifestations of tuberculosis were seen. On teasing out some of the nodules minute arthropods were found, which were subsequently identified by Dr. R. Hoeppli, of the Peiping Union Medical College, as mites probably belonging to the genus *Pneumonyssus*. The histological appearances are as follows:

The nodules consist of capsules, the walls of which are composed of cellular granulation tissue. The lumen of each capsule is lined by epithelial cells and usually contains an arthropod lying among cellular detritus. The tissue comprising the walls of the capsules consists of fibroblasts, leucocytes, eosinophils, plasma cells, and endothelial cells. Very little formed fibrous tissue is seen and no giant cells have been noted. A constant feature is the presence of heavy pigmentation due to granules lying within histocytic endothelial cells. This pigment does not give a ferrocyanide reaction, and since it closely resembles similar pigment visible within the gut of the parasites it is probably of faecal origin.

The eosinophils do not appear to be more numerous than is commonly seen in granulation tissue. Unfortunately, no haematological studies were done, so it is not known whether an eosinophilia was present in the peripheral blood.

The nodules are generally in close proximity to bronchioles, but in no instance could direct continuity be detected between a bronchiole and the lumen of a capsule. The surrounding lung tissue on the whole has a healthy appearance, although vascular congestion is excessive and erythrocytes are present within the alveoli in some areas.

The general features of a typical nodule, with a mite lying within it, may be seen in the accompanying photomicrograph.



Photomicrograph of a nodule in a monkey's lung. A mite is seen in section in the lumen of the capsule. (×50.)

Dr. Hoeppli drew my attention to a paper by Weidman (1915) giving a systematic description of similar acarids found in the lungs of a *Macacus rhesus* monkey in Philadelphia. That paper also gives a bibliography of earlier reports of acarids found in the lungs of monkeys.

Comment

The demonstration in monkeys of pulmonary lesions due to mites might be held to lend strong support to the concept of pulmonary acariasis in man. It should be borne in mind, however, that the life histories of the species of mites infesting the lungs of monkeys have not been established (so far as I am aware), and that it is not improbable that these mites may normally exist as ectoparasites on the skin of the host. Should this be the case, the habits peculiar to simians present an obvious explanation of how the parasites may readily be aspirated into the air passages. Nevertheless, if man be exposed to environmental conditions resulting in the aspiration of extraneous mites, it would be reasonable to suppose that, as in monkeys, structural lesions may ensue. That such lesions may give rise to symptoms requires no great stretch of imagination.

It is of interest to note that Soysa and Jayawardena (1945), in connexion with the radiological findings in their cases of asthma associated with mites in the sputum, describe "a remarkable mottled effect produced by small, discrete, ill-defined spots disseminated throughout both lung fields." It would seem likely that these shadows resulted from lesions similar to those described in the monkey.

Pending the opportunity for post-mortem investigation of human cases, the experimental production of pulmonary acariasis in monkeys might be expected to throw further light on the problem.

FULMINATING GAS GANGRENE

A FATAL CASE WITH UNUSUAL ACCOMPANYING FEATURES

BY

C. J. CELLAN-JONES, F.R.C.S.Ed.

Lieut.-Col., R.A.M.C.

AND

E. M. GRIFFIN, M.B., B.Ch.

Major, R.A.M.C.

During the war the risk of gas gangrene has been minimized by prompt and careful surgery and by the routine employment of serum and bacteriostatics. Nevertheless sporadic cases are still encountered, and occasionally, as in the following instance, the infection progresses so rapidly that treatment is of little avail.

Clinical History

On Sept. 9, 1944, during an aerial bombardment in North Italy, Cpl. B., aged 24, sustained a large penetrating wound of the upper and outer aspect of his right thigh. The injury was complicated by a fracture of the right femur involving the great trochanter and the neck of this bone. Eight hours later, at a field surgical unit, Major Birt carried out a thorough wound toilet, introduced calcium penicillin locally, and applied a Tobruk plaster. Sulphanilamide was administered by mouth to a total dosage of 14 g. The patient was transported by air to a base hospital, arriving at 3 p.m. on Sept. 11.

When we examined him shortly after his arrival he was obviously very ill, and intense toxaemia was evidenced by a pulse rate of 140 a minute and a subnormal temperature. In addition there were transient delirium, mild jaundice, and coldness and pallor of the right foot. The Tobruk plaster had been admirably applied and split before admission, and since further loosening failed to restore circulation, it was clear that the femoral artery had been damaged or obstructed. Transfusion of plasma, followed by two pints of whole blood, did not bring appreciable improvement, and as the systolic blood pressure remained in the neighbourhood of 90 mm. Hg we decided against operative intervention. The appearance of the wound and crepitation in its vicinity indicated that gas gangrene had arisen, and penicillin was therefore administered intramuscularly (200,000 units in 36 hours).

On Sept. 12 the patient's general condition was distinctly worse (temperature 101° F., pulse rate 150). He had become much more deeply jaundiced than is usual in toxaemia, and the picture was further confused by the discovery of malaria parasites (B.T.) in the blood films. During a subsequent lucid period he was able to inform us that he had suffered from malaria on five previous occasions.

Later in the day gas could be felt crepitating in the tissues of the abdominal wall and the right foot became frankly gangrenous. That night the patient sank into coma, and death occurred at 11 a.m. on Sept. 13—44 hours after admission to hospital.

Main Post-mortem Findings

During the necropsy gas was readily expelled from the tissues in the neighbourhood of the wound, and the whole of the anterior abdominal wall crepitated on pressure. Later the subcutaneous tissues were seen to be heavily bile-stained and there were areas of gas formation throughout the abdominal musculature.

Gangrene of the right leg was found to have resulted from a large ante-mortem clot which blocked the most proximal two inches of the femoral artery. There was no evidence of vascular trauma. Via the femoral canal, gas had passed upwards, distending the whole length of the psoas sheath. It was also present in large quantities in the loose tissues around the ascending colon. The cystic duct was so acutely kinked by gaseous inflation of the neighbouring tissues that the tense gall-bladder could not be emptied. Owing to the manipulation entailed, it was not possible to estimate the degree of compression exerted on the common bile duct. The liver was pale, and fatty degeneration had obviously occurred. There was moderate enlargement of the spleen, and its pulp was firm, with prominent trabeculae.

The only pulmonary pathology was a terminal basal pneumonia, but the thorax had been invaded by gas bubbles via the right side of the diaphragm and the right pectoral muscles were heavily infected. The left ventricle of the heart was collapsed and the myocardium was pale and friable.

It was not possible to culture specific organisms from the wound, but sections of liver provided interesting information. Well-marked dilatation of the hepatic ducts and generalized granular degeneration of liver cells were observed. Frequent areas of focal necrosis contained nests of rod-shaped bacilli which were presumably *Cl. welchii*. Sections of the kidney proved surprisingly normal; toxic changes were obvious, but no areas of focal necrosis could be detected.

Summary

In spite of careful and comparatively early treatment of a large wound, followed by the introduction of calcium penicillin, gas gangrene arose and caused death within four days.

Points of particular interest were: (1) The coexistence of toxic and obstructive jaundice. (We have never before observed displacement and kinking of the bile ducts by an accumulation of gas.) (2) The concentration of the infective process in the liver with comparatively slight renal damage. (3) The coexistence of anaerobic gangrene and gangrene resulting from vascular occlusion. (4) The fact that the patient's resistance was almost certainly lessened by frequent attacks of malaria.

We are grateful to our commanding officer, Col. R. A. Stark, for permission to report this case.

Medical Memoranda

Carotinaemia in the Tropics

The first record of carotinaemia in the Tropics was that of Sequeira (1936), who diagnosed the condition in two Europeans resident in East Africa. They had a marked yellow discoloration of the skin of the palms, the palmar aspects of the fingers, and the soles and heels. The clinical diagnosis was corroborated by the pathological findings. A careful investigation of their diets failed to reveal any cause for the condition. In the same paper there was reported the occurrence, in a male adult of the Muganda tribe, of a similar yellowish discoloration of the skin of the palms and soles. The diet of this African was also investigated, and was found to be the normal native diet, consisting mainly of plantains. On clinical grounds it appeared to be a case of carotinaemia, but it was not possible to test the blood serum for carotene.

A further five cases, all in Europeans—two from Kenya, two from Nigeria, and one from India—were described by Manson-Bahr and Ransford (1938). In all five the carotene pigment was demonstrated in the serum. In none of them was there any definite evidence of excessive consumption of foods with a high carotene content. Four of the cases gave a history of intestinal infection, and all were distinctly below the normal standards of health. The authors state that they had never observed carotinaemia among perfectly normal individuals who had returned after prolonged tropical residence. This condition of physical impairment with carotinaemia is directly contrary to the experience, in England, of Almond and Logan (1942), who found no evidence of ill-health among their cases.

Case History

In 1943 a Grenadian planter aged 45, of African descent, medium brown complexion, was sent to me for an opinion as to the cause of his condition; provisionally diagnosed as atypical jaundice. He stated that for approximately 10 years he had suffered from a persistent yellow discoloration of the hands and feet; apart from that his health had been excellent. He was residing in a malaria-free district and had not had an attack of malaria for over 20 years.

The palms of the hands showed a marked orange-yellow tinge; this was less noticeable, though still plainly evident, on the palmar aspects of the fingers. A considerable degree of discoloration was present on the soles of his feet. The sclerotics were clear, the urine normal, and the blood pressure 120/80. On general examination nothing abnormal was noted beyond a faint suggestion of an orange tinge in the skin, particularly that of the face. This very slight alteration in colour, combined with the natural degree of pigmentation, gave him an appearance of good health far above the average. On being questioned with regard to his diet he said that he was particularly fond of papaw, of which he consumed from 3 to 5 lb. daily. Miller and Robbins (1937) estimated that papaw (*Carica papaya*) contained, on the average, 2,500 international units of vitamin A per 100 g. of edible material.

The three-layer test was applied in which equal quantities of serum, alcohol, and petroleum ether were shaken up in a test-tube and then left to settle. Lipochromes were found to be present in abnormal amount, since the top layer had a strong yellow tinge. Greene and Blackford (1926) stated that this positive result was pathognomonic of carotinaemia.

I am indebted to Dr. J. Whiteman, D.M.O., Grenada, for bringing this case to my notice.

E. Cochrane, M.D., D.P.H.,
Senior Medical Officer, Grenada.

Two Cases of Erysipeloid treated by Penicillin

The administration of sulphonamides is generally very effective in the treatment of erysipeloid. The response to treatment by penicillin would appear to be prompt and rapid.

Case Histories

Two Army cooks, aged 42 and 34 respectively, were cutting up a carcass of fresh veal; one already had a small non-infected abrasion of the left ring-finger, the other cut his left middle finger during the process. Inflammatory swelling of the affected fingers began around the sites of trauma on the following day, being accompanied by sensations of stiffness and aching. On the eighth day of the illness the clinical picture in each patient was almost identical. The whole of the affected fingers including the knuckle and a small area of the palm of the hand, together with the contiguous sides of the proximal phalanges of adjacent fingers, was the site of a slightly tender bluish-red erysipeloid. A firm margin to the swelling could be traced, and flexion of the affected fingers was minimal and painful to perform. The epitrochlear and axillary glands were not clinically enlarged, and there was no constitutional disturbance.

Sodium penicillin was given intramuscularly—15,000 units as the initial dose and 15,000 units 3-hourly until totals of 485,000 units and 560,000 units had been administered. In each case after 24 hours the swelling had markedly decreased, flexion of the finger was easier, and the aching sensation and tenderness had practically gone. On the third day penicillin therapy was stopped; the definite edge of the swelling could no longer be detected, and flexion of the finger was almost complete. By the fifth day there remained only a slight discoloration of the skin over the affected area, and a collar of desquamation of the epidermis around the small traumata which had been the original entry points of the infection.

I wish to thank Col. T. F. Arnott, O.B.E., T.D., R.A.M.C., for permission to publish these notes.

G. A. Hodgson, D.M.,
Major, R.A.M.C.

Sir Farquhar Buzzard visited Leeds on March 16 for a meeting of the Provincial Hospitals Regionalization Council of the Nuffield Trust, held at the General Infirmary at Leeds. The Council had previously had a number of consultations with representatives of the voluntary hospitals, meeting the Lord Mayor of Leeds, members of the City Council, and others concerned with the co-ordination of hospital services. A report was made to the Council in regard to the development of two joint bodies in furtherance of the co-ordination scheme with which the Trust is associated. The first of these is in Gloucestershire, Somerset, and Wiltshire; the second concerns the formation of a joint body for the Essex area; they will receive and consider reports of the surveys of hospital services in their areas. The Council was addressed by Mr. William Gissane, clinic director and surgeon-in-chief of the Birmingham Accident Hospital.

Reviews

SUPERVOLTAGE X-RAY THERAPY

Supervoltage X-ray Therapy. By Ralph Phillips, M.S., F.R.C.S., D.M.R.E. With the technical assistance of G. S. Innes, B.Sc., A.M.I.E.E. A report for the years 1937-1942 on the Mozelle Sassoon Supervoltage X-ray Therapy Department, St. Bartholomew's Hospital. (Pp. 141; illustrated. 16s.) Published for the Sir Halley Stewart Trust by H. K. Lewis and Co.

This report on the experience at St. Bartholomew's Hospital with the million-volt apparatus merits a high place in the world literature on radiotherapy. The vision and scientific enthusiasm displayed by the members of the Radium Committee of the hospital since 1919 culminated in this project, which was inaugurated in 1934 after members of this committee visited the Sheffield Radium Centre to see the new continuously evacuated 200 kV *x*-ray apparatus installed by Metropolitan-Vickers, and the result was what is probably the most efficient supervoltage *x*-ray apparatus in the world for medical work. Finzi, Donaldson, Canti, Levitt, and Hopwood are to be applauded for the decisions which made this possible.

The account of the building, the apparatus, and the protection equipment is lucid, and the account of such technical matters as the devices employed to raise the operating voltage from 700 kV to 1,000 kV shows great ingenuity. The physical measurements for protection, voltage, half-value layer, and depth dose provide unique data of great scientific value, while the technical modifications carried out from experience in the department to improve on the details of design betray a high desire for a safe, accurate, and efficient clinical instrument and ingenuity in achieving it. The great gain over 200 kV apparatus is in the dose which can be given at a depth, especially with small fields (100% gain at 15 cm. with a 24-square-centimetre field).

As is to be expected, the number of patients treated during the five years covered by the report, encroached on as the work was by numerous essential physical measurements, justifies no more than a preliminary account of the clinical side of the work; but in rectal carcinoma the results reported show such an improvement on those of ordinary 200 kV *x*-ray therapy that (whether due to the improved depth dosage of 1,000 kV or to the different wave-lengths of radiation employed) the installment of a 1,000 kV apparatus in every large centre should be considered a necessity. Only a trial can show whether the use of 5 million volts suggested by the author will offer further clinical benefit. Developments in technique with the million-volt apparatus are still possible and necessary in his view.

The work of Mr. Ralph Phillips and of Mr. Innes, his physicist colleague, as set out in this profusely illustrated report cannot be praised too highly. They have built well on the basis afforded by the manufacturer's efficiency and the imagination of the committee.

TROPICAL MEDICINE

Stitt's Diagnosis, Prevention and Treatment of Tropical Diseases. By Richard P. Strong, M.D., Sc.D. Vols. I and II. Seventh edition. (Pp. 1,827; illustrated. $21.00 or £5 5s.) Philadelphia: The Blakiston Company; London: H. K. Lewis & Co.

That the demand for this textbook has increased in recent times is evident from the fact that the new (seventh) edition, at the end of 1944, follows so soon after the previous one, which was published only in 1942; even better evidence of its popularity is that between these editions three reprintings were required. This access of interest in the diseases of tropical countries on the part of medical men in America is no doubt primarily attributable to the urgent need for providing for the medical conduct of campaigns in tropical regions. It is not improbable, however, that the demand for information about tropical diseases will persist and even increase in peacetime; certainly the need will remain.

The effort to keep a book of this kind abreast of the times involves an immense amount of reading and research, and the author has been particularly successful in presenting the advances made up to date: for example, the use of sulphaguanidine and similar drugs in bacillary dysentery, and the experimental work relating to the various applications of penicillin in tropical diseases. Some of the most striking recent work has been done on the aetiology of pinta or carate; pinta is now regarded as a spirochaetal disease due to *Treponema herrejoni*. This adds yet another complication to the syphilis-yaws series of problems in the Tropics.

In some directions progress in medical science during the latter part of the war has been so rapid that a few omissions and additions could be made with advantage; for information about certain advances quite recent journals will have to be consulted. This affects principally the sections on treatment and prevention: cases in point are the fresh conclusions as to the disadvantages and even dangers of intensive alkaline treatment of blackwater fever; the effects of improved discipline in the prevention and cure of malignant tertian malaria; and the new means applicable for the reduction of insect-borne disease in general, in regard to which a good deal of additional knowledge has been accumulated in recent months. These small and unavoidable drawbacks do not in any way affect the fundamental value of this standard textbook. The high level already established for it has been admirably maintained by Prof. Strong, who is again responsible for the new edition.

A SYMPOSIUM ON UROLOGY

Clinics. Volume III. June, 1944; No. 1. Edited by George Morris Piersol, M.D. (Pp. 249; illustrated; six volumes per year; commencing with June number. £4 10s. per six volumes.) London and Philadelphia: J. B. Lippincott.

Six volumes of this publication are to appear yearly, and the volume under notice contains a symposium on urology. It gives an excellent account of the work done on this subject in the various clinics of North America. Dr. L. Herman, for example, summarizes work done in Philadelphia on endocrine therapy in carcinoma of the prostate. He has come to the conclusion that, although there is no reason to believe that either castration or stilboestrol therapy increases the span of the patient's life, it undoubtedly relieves him of much pain and discomfort. Opinions would seem to differ as to the relative advantages of these two methods of dealing with prostatic carcinoma. Another subject considered in this volume is the preventive treatment of calcium urolithiasis. Renal calculi are very frequently formed by patients confined to bed for many months by some bony injury, and, as thousands of wounded soldiers at the present time are suffering this fate, any measures which counteract this disposition to form stones are of great importance. Dr. Herman considers such factors as calcium excretion, change in the pH of the urine, diet, infection, and immobility in bed in the formation of stones. He recommends the following: increased fluids, control of the diet with regard to vitamin A and calcium content, movement of the patient, vigorous treatment of infection, and continuation of these measures for at least three months after the patient has got up. He also advises that a skiagram should be taken as a routine before patients who have been long in bed with fractures are discharged from hospital.

Some of the papers published in this volume deal with rarities only. There is also a very good account of the management of syphilitic patients by Dr. F. Halz and Dr. L. P. Ereaux of Montreal. In spite of the fact that public clinics deal with great numbers of syphilitic patients, the future of the conquest of syphilis rests in the hands of medical practitioners. The object of this paper is to give practitioners and medical students an up-to-date summary of the diagnosis and treatment of this disease.

CARE OF THE FEET

Take Care of Your Feet. Decorations by Francis Barthropp. (Pp. 129. 5s.) London: Published for the Foot Health Educational Bureau by George Gill & Sons, Ltd.

In an effort to make the public more foot-conscious the Foot Health Educational Bureau has published a book for popular reading entitled *Take Care of Your Feet.* It is a peculiar paradox in the use of words that the aim is really to make the public less conscious of their feet—a very worthy motive, not, however, so easy of accomplishment. Perhaps the first book of this kind to appear was in the United States, when Dr. D. Morton, whose anatomical and morphological work on the foot is well known, produced *Oh, Doctor, My Feet,* a popular exposition of his views on the functioning of the feet.

We cannot honestly say that we consider the public will derive much guidance, even if they get entertainment, from

Take Care of Your Feet. As the preface correctly states, "the astonishing thing is how little care is needed, how much can be achieved by simple common sense." The trouble is that even now we know too little about the functioning and variations of the feet to be in a position to give authoritative advice except on the simplest matters, such as cleanliness and the need for freedom from foot distortion by ill-fitting footwear. But these matters are already common knowledge to the great majority of people. If anyone be inclined to doubt the truth of such an indictment of the present state of our knowledge let him read the very divergent views of the more eminent orthopaedic surgeons on the aetiology of almost any foot trouble, and he then must agree that there is little consensus of opinion to justify *ex cathedra* advice upon how to avoid foot troubles. Indeed the author of one widely read book on the foot (Lake) has advanced the view that some foot disabilities have their roots deep-seated in inherent evolutionary weaknesses in the architecture of the foot, and are only partially dependent upon the immediate environment. If there be any truth in this idea such disabilities cannot be entirely avoided by the mere application of any rules of hygiene.

But whatever criticisms may be made of the general aim of the book, the individual items and illustrations should prove both interesting and informative to the public, since they are easy to understand and the language is non-technical. Contributors to the symposium—for such it is—include orthopaedic surgeons and doctors, chiropodist, physiotherapist, shoe manufacturer and fitter, tanner—there is even a chapter on "How to Clean your Shoes"! The book will almost surely have a wide range of readers, and we hope that they will not feel any sense of frustration when they have finished it.

Notes on Books

History has proved that war, so destructive of much else, has a constructive influence on medicine. This is reflected in the new editions of well-known textbooks that are appearing. The fourth edition of Prof. CARL J. WIGGERS's *Physiology in Health and Disease* (Henry Kimpton; 50s.) illustrates that fact. As he expresses it, the present emergency "has challenged physiologists to interpret not merely the experiments which Nature makes on man (disease), but also those which, through warfare, man inflicts on himself." And with that as his text he has largely rewritten his book to useful purpose.

An attractive pamphlet entitled *Life Blood*, the official account of the transfusion services, has been prepared by the Ministry of Information for the Ministry of Health and the Department of Health for Scotland. It is published by H.M. Stationery Office at 6d. and is meant for popular consumption, as may be judged from the section headings: (1) From blood-giver to battlefront. (2) What is blood? (3) Transfusion: a life-saving service. (4) Blood relations: the story of the blood group. (5) How blood is given. (6) The secret of plasma. (7) The gift works miracles. The illustrated cover and the group of photographs in the middle of the pamphlet are good examples of reproduction by gravure process.

Preparations and Appliances

A NEW COVERING FOR SKIN DRESSINGS

Dr. J. E. M. WIGLEY, F.R.C.P., writes:

For many years I have been far from satisfied with the usually accepted methods of covering areas of crusted, exuding, or even pustular inflamed skin when it is desired to keep some external application in contact with them, and I expect that many of my colleagues have had the same feeling. By these usually accepted methods I mean the placing, over the desired application, of a layer of gauze, linen, or possibly lint, and then trying to keep these in place with bandages. It is generally found that when the dressing is to be renewed in 12 or 24 hours, or even longer, the medicament has dried or largely disappeared, and the gauze or other material has stuck to quite a lot of the affected area. When this is removed, either by simple traction or by soaking, it is almost invariably found that a considerable amount of the inflamed area, and perhaps newly growing epithelium, is pulled away with it, and consequently that the healing process is at least temporarily delayed.

When about a year ago I saw a film which showed the various uses that the Bunyan-Stannard envelopes could be put to, in addition to their use for the irrigation treatment of burns, I specially noticed that the material of which these bags were made (i.e., Stannard silk) did not adhere to the surface of the skin, whether that surface were normal or inflamed and crusting and oozing. In answer to a question to the demonstrator of the film it was confidently asserted that this Stannard silk would not stick to such surfaces, and it occurred to me that it might be more than a useful covering for such dressings as are often employed in the treatment of various skin eruptions. The eruptions I had in mind were principally of an eczematous nature affecting large areas of limbs, as in varicose eczema; on very mobile parts of the body, such as eczema of the breasts; and the frequently troublesome condition known as pus-coccal dermatitis, or possibly dermatitis repens. I was able to obtain, through the helpful and enthusiastic co-operation of the manufacturers of the irrigation envelopes, specimens of this silk in different shapes and sizes. Included in these specimens were some loose-fitting gloves.

My first experience with this material was that, though it did not stick to any skin surface to which it was applied, it was very apt to prove too hot owing to its non-porous consistency, and hence either it required frequent changing or it increased the irritation so much that the patient could not tolerate its use. As a result of various conversations with the manufacturers I have found that this defect has been almost entirely overcome by perforating the silk moderately closely. This perforated silk has now been in use in the out-patient department of St. John's Hospital for Diseases of the Skin, 5, Lisle Street, Leicester Square, W., for about five or six months, and I have also used it in my wards at Ashridge Hospital. On the whole I have found it very successful, though of course it needs to be used with a reasonable amount of common sense. We have found it better to try to fix the silk as lightly as possible with a bandage (avoiding any cotton-wool) rather than to use "elastoplast" or other adhesive strapping, as so many patients' skin eruptions are apt to be aggravated by these things. My usual method of using the silk is as follows:

Whatever application is desired, whether it be lotion, cream, paste, or ointment, is applied direct to the area to be treated and then the Stannard silk, cut to a suitable size, is placed over the ointment. In treating eczema of the breast I have found it eminently satisfactory to stitch the appropriately cut piece of Stannard silk to the inner surface of the brassiere. I know that it does not entirely prevent mobility of the breast, but the movement on the non-adherent surface of the Stannard silk does not seem to matter.

Stannard silk consists of a sheet of fine silk impregnated with a certain resin. It is claimed to be reasonably durable, and I have found that one piece of silk can be used, even by out-patients who do their own dressings, for about three weeks. For cleaning the silk it is only necessary to use warm water and soap, and I think on the whole it is undesirable to put it into the usual routine antiseptics. I say this, not so much that the antiseptics may destroy the silk, but that a small quantity of antiseptic may be left in contact with the silk and thus applied to the inflamed skin, which it may irritate and so make the underlying condition worse.

The manufacturers of this silk are Irrigation Envelopes Ltd. of 345, Gray's Inn Road, W.C.1, whom I have found more than willing to co-operate in any way they can. They are proposing to make a silk in rolls of two widths which could be conveniently hung on the wall and cut off in various lengths and sizes as necessity arises. The relative cost of the Stannard silk works out as very little different from that of the gauze, etc., which would require so much more frequent changing.

LONG-ACTING SOLUTIONS FOR INJECTION

Allen and Hanburys Ltd. announce the introduction of the "hyperduric" series of long-acting injectable solutions. In these preparations the usual acid radicals are replaced by mucate. It has been found that combination in this way with mucic acid has the effect of delaying and prolonging the absorption and the action of the base. The series consists at present of the following: Hyperduric M.H.A.—morphine, gr. 1/4, hyoscine, gr. 1/80, adrenaline, gr. 1/160, per c.cm., giving about 8 hours' amnesia and narcosis without fall of blood pressure, for pre-operative medication, "twilight sleep" in labour, and relief of traumatic pain and shock; hyperduric morphine—gr. 1/2 per c.cm., giving 8 to 12 hours' analgesia in inoperable malignant neoplasms, visceral lithiasis, wounds, and acute and chronic inflammatory disorders; and hyperduric adrenaline—1 in 1000, giving 8 to 10 hours' relief in bronchial asthma and other allergic disturbances, including anaphylactic (e.g., serum) shock, besides surgical shock.

NETHERLAND CHILDREN IN ENGLAND

BY

J. TAUBER, M.D.Prague, U.N.R.R.A.

Four hundred and ninety-six Netherland children reached this country on Feb. 11, 1945, and were accommodated in a large hostel in Coventry formerly occupied by immigrant munition workers. Preparations for their reception had been made some time in advance. We had little previous knowledge of the condition of the children except that they had been living for a long time mainly on bread, potatoes, and cabbage, and that in this first contingent there were to be no severe or hospital cases.

There is little practical information in medical literature about the feeding of malnourished, weakened, but not really sick persons. It was known that persons who have had practically no fat in their diet for years become very sensitive to it, and that they are liable to react to fat with severe gastric disturbance. In "feeding up" a large group of children, with only a short time available for treatment, it is nevertheless essential to ensure that the fat content of the diet is not kept too low. It is necessary to find the optimum level of tolerance. "Carbohydrate poisoning" is a term that has been used to describe the effects of the type of diet these children had had. It was decided to limit the initial daily fat intake to 50 grammes per child and the initial daily carbohydrate intake to 400 grammes (to include 250 grammes of bread). The first menus, however, were prepared with an initial daily fat intake of about 28 grammes.

The children were mostly between 7 and 15 years of age: three were 16 years old. On arrival they presented a somewhat different picture from that expected. The main feature of the malnutrition was not so much wasting as the general undersize. Pallor was notable, and many children were rather weak. The apparent age of many children was well below the actual age. Gross symptoms of avitaminosis were not found. Some children had local thickening, cracks, or dryness of the skin. No trophic changes of the nails were observed and no diseases of the hair. Some 5% of the children had somewhat swollen gums. The dental state in general was not unsatisfactory.

The children's clothing was old, worn, and torn. Their shoes were in a worse state. Several of the children had dresses and suits made from Army blankets given them by soldiers of the liberating armies. Many had all-wooden clogs only. Their socks were very ragged. Within 24 hours the Women's Voluntary Service had started the distribution of complete outfits of new clothing (including handkerchiefs, towels, face-towels) supplied by the Red Cross. It was most pathetic to see the children's pleasure with their new belongings.

Despite the severe shortage of soap on the Continent, the children were very clean on arrival: care had been taken of this before they left the Continent, and the few cases of infestation with lice as well as cases of scabies were treated.

The amount of food was increased each week as tolerance was established. At first many children complained of hunger, which is not surprising. The initial diet had a daily calorie value of 1,800. This was increased on the third day to 1,900, on the fourth to 2,000, on the fifth to 2,200, and at the end of the first week was 2,400 calories. It was difficult to control the diet strictly because well-meaning visitors to the hostel gave sweets, biscuits, and cakes to the children unknown at the time to the authorities.

Acute gastric disturbance occurred in 17 cases during the first week, 27 in the second week, 24 in the third, and only 7 in the fourth. Most of the cases were easily controlled, although 4 cases developed jaundice. Sores on the feet and hands and impetigo were the commonest visible lesions. It was noticed that many cuts and wounds had turned septic. There were 5 cases of bronchitis and 6 of nocturnal enuresis.

The approximate average gain in weight of the children is shown in the accompanying Table.

While living in occupied Holland the children—the older ones at all events—had often been encouraged by the parents to defy German authority and to perform small acts of sabotage—such as, for example, the puncturing of tyres of enemy military vehicles. When transferred to the hostel in England the children suddenly found that law and order had to be observed, and at first they found the change somewhat bewildering. During the first week or so "sabotage" tendencies were noted in a few boys of the 13–15 years age group. All soon conformed happily to the necessary routine and rules of hostel life.

This first contingent of Netherland evacuee children on the whole presented few difficulties. The main problem was to determine and control the diet, and to graduate it according to growing tolerance. An interesting but lesser problem was the disciplining of the older children, who had for long cultivated disobedience to the German authorities in occupied Holland.

I would like to thank the M.O.H. of the City of Coventry (Dr. A. Massey) for his valuable help and advice in connexion with the medical work at the hostel, and Col. Daubenton for his kind permission to publish this report.

BRITISH AID FOR RUSSIAN HOSPITALS

Mrs. Churchill's Red Cross "Aid to Russia" Fund, which was started towards the end of 1941 and has now reached the impressive total of £6,700,000, is to have a permanent memorial in the shape of two hospitals at Rostov-on-Don, the port on the Sea of Azov in the Northern Caucasus. It was originally proposed to have one hospital of 1,000 beds, which, after the war, would be available for members of the Services and civilians alike, but on a suggestion from Moscow it was agreed to equip two hospitals, each of 500 beds. A committee, under the joint chairmanship of the Presidents of the Royal College of Physicians and the Royal College of Surgeons, and including hospital administrators, nurses, and representatives of the Ministry of Supply and the Ministry of Health, was set up for the purpose of advising on equipment. The equipment has been scheduled in 16 sections, ranging from the medical and surgical installations appropriate to hospitals of the size named down to motor transport for both hospitals, and the Ministry of Supply is now engaged in placing the orders. The total cost will be about £400,000, half of which has been contributed by the Scottish Branch of the British Red Cross Society. Mrs. Churchill is going to Russia on the invitation of the Soviet Government and the Soviet Red Cross and Red Crescent, and proposes to visit Moscow, Leningrad, Stalingrad, and Rostov, the rehabilitation hospitals in the Crimea, and the spa hospitals in the Caucasus. Mrs. Churchill's committee has also agreed to provide the machinery and equipment for a Russian "Roehampton" for artificial limbs; this is being built at Moscow, with a subsidiary centre at Kharkov.

At a press conference in London Mrs. Churchill explained the purpose of her visit, and Lord Moran and Sir Alfred Webb-Johnson spoke briefly, the former mentioning his own visit to Russia, in which he had been greatly impressed by the thoroughness of the hospital organization and equipment, and the latter saying what pains had been taken by the committee of experts to ensure that these two hospitals at Rostov, a permanent memorial of the gesture made by the British people towards the Russian people during their common sufferings, were equipped with the best that could be provided. The bulk of the equipment will be British, but the committee has not confined itself to British equipment if something better can be obtained elsewhere. Prof. Sarkisov, the representative in Britain of the Soviet Red Cross and Red Crescent, expressed his appreciation of what had been done. It was mentioned that up to date the Fund has sent, in 42 shipments, nearly 14,000 tons of drugs, hospital equipment, and comforts for the sick and wounded of the Soviet Armies.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY APRIL 7 1945

PRIMARY ATYPICAL PNEUMONIA

The literature of the past eight years has contained a growing number of reports of an acute epidemic respiratory disease characterized by an influenzal onset, rapid prostration, and clinical and radiological evidence of lesions in the lung; the disease resolves spontaneously in a few weeks and the mortality is low. It is probable that this condition has existed sporadically for many years,[1] but recently it has become increasingly common, first in America and later in this country. The early reports, such as that of Bowen[2] in 1935, came from America, and, as the evidence accumulated, certain facts about the disease emerged. The incidence is particularly high among young adults, and epidemics often occur in communities of young people; there have been outbreaks among university students and hospital staffs, and in Army camps. Weir and Horsfall[3] succeeded in recovering from patients suffering from primary atypical pneumonia a virus that caused pneumonia in the mongoose, while Adams[4] found cytoplasmic inclusion bodies in post-mortem specimens. The disease has been transmitted to human volunteers by inoculating them with a filtrate of sputum and throat washings collected from 6 cases of atypical pneumonia.[5] Three out of 12 men developed the disease. Other facts suggesting that a virus is the infecting agent are the long incubation period of two to three weeks, failure to find causal bacteria, and the peculiar pathological changes in the lungs, which resemble those seen in known virus pneumonias.

Primary atypical pneumonia was comparatively uncommon in Great Britain before 1940, though sporadic cases were seen, some of which Scadding[6] described in this *Journal* as "disseminated focal pneumonias." Virus pneumonia, primary virus pneumonitis, atypical pneumonia, acute influenzal pneumonitis, and acute interstitial pneumonitis are a few of the terms given to the condition. In spite of the efforts of certain workers, notably Burrell[7] and Scadding,[8] to evolve a rational classification of the pneumonias based upon facts, the indiscriminate and confusing use of names continues. Some of these—particularly the misleading synonym "pneumonitis"—have been employed by various authors to denote different conditions, and almost every new worker in this field has invented some name to suit his fancy. Pneumonia has a long-established claim to be the generic term for inflammations of the lung, and for the sake of clarity "pneumonitis" and its companion "pleuritis" should be discontinued. In 1942 a Commission on Pneumonia of the United States Army[9] tried to bring order out of chaos by decreeing that the new epidemic disease should be called "primary atypical pneumonia, aetiology unknown." The adoption of this rather clumsy title would undoubtedly help to prevent confusion in the future.

Primary atypical pneumonia is now a common disease on both sides of the Atlantic; in 1943 Drew, Samuel, and Ball[10] published a very full account of 50 cases among Service personnel in this country, and since then American authors have recorded even larger numbers. The clinical, radiological, and pathological aspects of the disease can now be described with accuracy. There is often a prodromal cold, followed in about a week by the sudden or gradual onset of prostration with high fever; a paroxysmal cough and substernal soreness are almost always present at this stage. The sputum is muco-purulent and rarely stained; it contains the usual bacterial flora but pneumococci are never numerous.[11] Varying degrees of dyspnoea and cyanosis may be present, and headache is often a feature. There may be no abnormal physical signs in the chest, and the leucocyte count is usually normal. The disease may last from 3 to 5 weeks and recovery is the rule. Some outbreaks have been more serious than others: in a series of 19 cases Brethauer and Thompson[12] recorded 5 deaths; pulmonary oedema, preceded by a fall in blood pressure, was a feature of these. Golden,[13] working in the United States Army Institute of Pathology, examined post-mortem material from no fewer than 90 fatal cases in 4 years. In the uncomplicated cases he found an ulcerative bronchitis and bronchiolitis with peribronchial interstitial pneumonia; a notable feature was the heavy monocytic infiltration of the affected areas. Patients with this condition are very prone to develop a secondary bacterial pneumonia, but exudation into the alveoli is rare in the uncomplicated cases except as a thin deposit which forms hyaline membranes on the alveolar walls. Acute interstitial pneumonia of this type has been reported during influenza epidemics by MacCallum[14] and by Scadding,[15] and it bears an interesting resemblance to the so-called rheumatic pneumonia (Epstein and Greenspan[16]). Bronchial dilatation occurs early in the disease, and although the destructive changes are rarely gross enough to prevent resolution to the normal state, examples of residual scarring, with bronchiectasis, have been recorded by Crysler[17]; there is, however, reason to believe that collapse may have been a complication in these cases.

The radiological appearances of primary atypical pneumonia are often striking and were largely responsible for its recognition. Crysler[17] and Lewis and Lusk[18] have now described them in detail. The infection first attacks the bronchi, and an *x*-ray film in the early stages shows some enlargement of the hilar glands with heavy truncal markings in the affected area, which in most instances extends downwards from the hilum into the lower lobe. As the infection spreads into the interstitial tissues of the lung two types of shadow may be seen—a homogeneous, ground-glass opacity through which the lung markings are still visible; or a group of patchy flocculent opacities. These may vary in size from large blotches to an almost miliary mottling, as in the disseminated focal pneumonia of Scadding. The affected area usually occupies only part of a lobe and tends to follow the bronchial distribution; a lateral view is often useful in determining its situation. Bilateral lesions occur in about 20% of cases. As the pneumonia resolves, the opacities become less dense and take on a moth-eaten appearance. The large, homogeneous type of lesion may resemble that of tuberculosis, collapse, a lung abscess, encapsulated fluid, a neoplasm, or a bacterial pneumonia. The clinical picture, course of disease, and sputum examination will usually confirm the diagnosis, but Stein and Kresky[19] have shown that in pneumococcal pneumonia the radiographic appearance may be identical, so the diagnosis cannot be made from the *x*-ray appearance alone. Small wedge-shaped shadows, and even hazy diffuse mottlings, are often the sole radiographic changes in proved pneumococcal cases, and similar changes may be seen in the benign circumscribed pneumonia described by Ramsay and Scadding[8]: a transient opacity appears, usually in the lower lobe, during the course of a mild infection of the upper respiratory tract. Kennedy[20] lately recorded 100 cases of this disease, which may be distinguished from primary atypical pneumonia by the fact that it causes almost no constitutional disturbance, and the *x*-ray changes usually clear up in about 7 to 10 days. The flocculent shadows seen in primary atypical pneumonia may resemble an area of tuberculous infiltration, miliary tuberculosis, or a bacterial bronchopneumonia.

Primary atypical pneumonia is becoming more common. Although the disease is usually self-limiting and there is no specific remedy, symptomatic treatment should be carried out with circumspection, for the condition can become serious. The disease affects not only the entire respiratory tract but the whole body: oedema of the myocardium (Brethauer and Thompson[12]), infiltration and necrosis of the branches of the pulmonary artery (Kneeland and Smetana[21]), and encephalitis (Golden[13]) have all been recorded. The patient should therefore be kept in bed and every effort made to conserve his strength. A careful watch should be kept for signs of circulatory or respiratory distress, and oxygen should be given early if necessary. The sulphonamides are useless, except in those occasional cases in which a secondary bacterial pneumonia supervenes. As in influenza, weakness and depression, with a lowered resistance to infection, are features of the recovery period, and convalescence should be adequate.

DIAGNOSIS OF VITAMIN DEFICIENCY FROM LABORATORY TESTS

Of recent years many laboratory procedures for the measurement of vitamin levels in the blood and urine have been devised. What relation exists between the clinical picture of an early vitamin deficiency and such laboratory determinations? Much has been written on so-called subclinical vitamin deficiencies, particularly of vitamin C and the vitamin B complex, the diagnosis usually being made on a poor dietary history associated with indefinite symptoms such as weakness, nervousness, anorexia, irritability, and various gastro-intestinal complaints. It is often difficult to tell whether a patient has a true vitamin deficiency and may benefit from the intelligent use of a liberal diet supplemented with vitamins, or whether the patient suffers from mild ill-health or is neurotic. A correct diagnosis is obviously of importance to prevent expensive vitamin preparations being recklessly dispensed and wasted. It is estimated that the American public spends 20 million dollars a year on vitamins, for the most part unnecessarily. Vitamin deficiency is generally due to malnutrition, which is usually due to poverty. Those who cannot afford to eat enough certainly cannot afford vitamins out of a bottle.

Ruffin, Cayer, and Perlzweig[1] have done clinicians a service by correlating laboratory studies on the estimation of vitamins in blood and urine with the symptoms of mild clinical deficiency. They assessed the "vitamin status," as shown by laboratory tests, of patients with the clinical symptoms of mild vitamin deficiency, and compared the results with those obtained with controls chosen from hospital patients and from students, technicians, and dietitians. The latter group presumably represented the better-fed members of society. The difficulty arises when the results of such estimations are interpreted and normal values are laid down. What is the lower limit of normal? Ruffin and his co-workers arbitrarily took this as the upper limit found in the lowest 10% of the normal control group for each vitamin. This, of course, has no clinical significance and is only a base-line from which to work. The patients from the vitamin-deficient group showed statistically lower levels of vitamin A in the plasma than the normal and hospital controls, though no clinical evidence of frank vitamin-A deficiency was seen. There was a wide discrepancy in the vitamin-C levels of the plasma between the suggested lower limit of normal (0.15 mg. per 100 c.cm.) and the generally accepted figure of 0.6 mg. per 100 c.cm. This confirms the more recent view that plasma-vitamin-C studies are valueless for detecting vitamin-C deficiency. Nearly 50% of the normal controls had a plasma vitamin C below 0.6 mg. per 100 c.cm., which is generally thought to be the lower limit of normal. Actually the difference between the plasma vitamin C of the vitamin-deficient and the normal control groups was not statistically significant. The urinary excretion of nicotinic acid after a test dose of 500 mg. of nicotinamide averaged 48 mg. in the vitamin-deficient group and 88 mg. in the controls; most of the deficient group had values below the suggested lower limit of Ruffin and his colleagues (65 mg.). The urinary excretion values of riboflavin after a test dose of 5 mg. were statistically lower in the deficiency group than in the controls. Similar results were obtained with the excretion of vitamin B_1 four hours after a test dose of 1 mg. The levels for vitamin B_6 showed no significant variation between the normal controls and the vitamin-deficiency group: there is some doubt about the significance of vitamin B_6 in human nutrition. It is of interest to note that most patients in the deficiency group had levels below the suggested lower limit of normal in more than one vitamin. Thus 24 of 26 patients had levels below the suggested lower limit of normal in nicotinic acid, riboflavin, and vitamin B_1. This is in keeping with the clinical opinion that vitamin deficiencies rarely occur singly.

---

[1] *Gastroenterol.*, 1944, **3**, 340.

The observations of Ruffin and his colleagues suggest that, with the exception of vitamin C, there is a relation between the clinical picture of a mild or early vitamin deficiency and the results obtained from laboratory determinations of vitamin levels in the blood or urine. Now that the estimation of vitamins in body fluids is a practical procedure, this should become an important aid in confirming the presence of mild or early deficiencies, and save much of the money spent on useless vitamin therapy.

A TEST FOR TRICHINOSIS

The exact diagnosis of trichinosis in man is often a tedious and uncertain business, involving a muscular biopsy with the inevitable chances of a random sample failing to show parasites. There have therefore been, from time to time, attempts to evolve skin or serological tests which would simplify the diagnosis and make this more certain. The human disease usually resulting from the consumption of raw or ill-cooked infected pork, such tests might also be applied to the detection of the infection in pigs, and if satisfactory they would add a useful weapon for the control of infestation in these animals. The importance of having at hand such diagnostic measures varies with the incidence of the infection. This is not a common one in this country, though there have been a number of recent outbreaks, and it is likely that cases are not infrequently overlooked. It is, however, a widespread disease in the United States, though the exact incidence is uncertain, since the symptomatology varies with the degree of infestation, and, as a result, many cases of the disease, especially of milder infections, are undiagnosed; in fact, many of the victims may be almost symptom-free.[1] Wright and his co-workers[2] in 1943, by the post-mortem examination of diaphragmatic muscle, found 855 infected individuals out of 5,313 necropsies; 733 of these showed fewer than 11 larvae per gramme of muscle, while 38 showed more than 50. On the basis of these and similar figures Hall and Collins consider that there are several millions of persons in the United States who are infected.

Of the immunological tests, complement-fixation and precipitation tests have been widely employed since Ströbel[3] introduced the first in 1911. The results, however, though satisfactory in some hands, have been irregular, with false positives and failures of the test in undoubted cases of infestation. The reaction takes some time to become positive, and after reaching a peak its intensity diminishes as time passes. One of the chief technical difficulties in devising a satisfactory immunological test is the preparation of a suitable trichinal antigen. This is usually made from larvae which are obtained by the digestion of muscle from infested animals. Suessenguth and Kline[1] have now introduced a new flocculation test for this disease, similar in many respects to the latter's better-known microscopical slide-precipitation test for syphilis. The antigen is prepared from the trichinous muscles of artificially infested rats, which are submitted to peptic digestion to free the larvae; these are then collected, washed, dried, and subjected to extraction with alkali. The extract is cholesterolized, as is the Wassermann antigen, and under suitable conditions gives a specific flocculation with the inactivated serum of patient or animals suffering from trichinosis. The authors report their results in some 896 cases and think them satisfactory: only 13 of these were examples of trichinosis when clinical, histological, and immunological data were all considered, so that there is need for a more extended series of results before the value of a positive test can be properly assessed. Syphilitic sera gave uniformly negative results. A number of observations made on experimentally infected swine, together with a few on human beings in which it was possible to follow out the course of the infection, indicated that the test becomes positive about 3 weeks after infestation (this is about the stage at which the larvae in the muscles reach their full development) and that the peak of antibody production occurs between the 23rd and 55th days; a positive result was still obtainable 10 months after infestation.

It is evident that this test is essentially one for use in laboratories where a regular supply of material is likely to be available. The technical details are exact, though not complicated, but the results of an occasional test in inexperienced hands are not likely to be of much value.

ANTIMALARIA MEASURES IN INDIA

In a notice in this *Journal* of the annual report of the Ross Institute of Tropical Hygiene, India Branch, for the year 1942–3 mention was made of a summary by Dr. G. C. Ramsay of antimalaria measures that had been found effective in North-Eastern India. In the report for 1943–4[1] this summary has been brought up to date in the hope that it will serve the useful purpose of its predecessor in describing and illustrating the progressive antimalaria measures which the Ross Institute is able from experience to commend for adoption by subscribing interests, by the armed Forces, and by others concerned in the control of malaria in this region. Among such results of special experience stressed in the present report is the danger of surface drainage as an antimalaria measure where the vector species are *A. minimus* and *A. fluviatilis*. These species favour above all for their breeding places small sluggish streams or watercourses. An open drain may thus create an even more dangerous breeding-ground than the original swamp, which may have been relatively harmless because of covering vegetation. Again, drains effective when first made are apt to become dangerous by growth of grassy edges or other changes which occur in the course of time. Hence, as the report emphasizes, in the areas where *A. minimus* and *A. fluviatilis* are the chief carriers surface drainage should be so far as possible minimized, and where drains are necessary they must be constantly controlled by weeding, canalization, oiling, shading, flushing, herbage packing, or lining with cement. The use of shade over drains continues to be one of the most important measures, and attention is drawn to the "bee-hive" or "pent-house" pruning now being adopted in some districts. This gives the maximum amount of foliage, thereby further reducing the possibility of grass or weeds becoming established in the channels. An interesting photograph illustrates this method. Flushing by automatic siphon continues to grow in importance as a method of control, and some estates in South India formerly hyper-endemic are stated to be now practically free from malaria owing to flushing measures. Some remarks are made in regard to misconception as to the practical limits of this method, which are by no means confined to small installations. Photographs are reproduced of a large pipeless automatic siphon in action. The serious danger from irrigation, hydro-electric schemes, construction of railways and roads, and other sources of man-made malaria arising from engineering works is stressed and the suggestion made that engineers should receive training in antimalaria work. Though the report is commendably modest in size it is a most useful and helpful publication, and should be closely studied by all who are engaged in antimalaria work in these regions.

THE SMOKE ENEMY

At a joint conference in London of the Institute of Fuel and the National Smoke Abatement Society many technical aspects of the smoke nuisance have been discussed. The domestic hearth is well known to be the chief source of this evil, because in the open grate no attempt is made to control combustion, and although an excessive amount of air usually passes up the chimney the gases are too cold for the volatile matter to burn once it escapes from the fuel bed. Factory chimneys make a large contribution to the smoke-laden atmosphere, but in industrial fires there is generally a much better control over combustion, so that the smoke, for the same amount of bituminous coal burned, is less than with the domestic fire. Dr. G. M. G. Dobson, of the Department of Scientific and Industrial Research, told the conference that the annual deposition of soot in country districts is in places less than 10 tons to the square mile, whereas in industrial towns it may be 100 or 200 tons to the square mile, and in known districts there may be as much as 2,000 tons to the square mile in the year. The concentration of smoke and sulphur deposit in British towns is more or less proportional to the square root of the population. The provision of smokeless zones in itself is not an effective safeguard. Hyde Park is more or less a smokeless zone, but on days when the air of London is foggy there is nearly as much smoke in Hyde Park as anywhere else.

Major S. F. Markham, M.P., pointed out that the smokiest areas in cities show an infant death rate double that of sunny small towns, and the general death rate also is highest where the gloom is deepest. Even allowing for other important factors such as bad housing and overcrowding, the amount of respiratory diseases in polluted areas is extremely significant. Among the remedies or palliatives put forward by various speakers were statutory joint boards to approve small industrial fuel plants, a better education of stokers, and, of course, for domestic fires, the replacement of coal by smokeless fuel. A special point was made of railway smoke, which always seems particularly objectionable, but a representative of the L.M.S. claimed that this was an exaggerated complaint. Railway locomotives use only about one-thirteenth of the total coal consumed in this country, and they burn it with an efficiency of 70 or 80%, compared with an average for coal-burning in general of 25 to 30%. Nevertheless, it is good to learn that the railways are not complacent about the amount of smoke that comes from their funnels, and locomotive engineers are striving for still greater efficiency. Proposals for the setting up of smokeless zones are described in some detail in a new booklet published by the National Smoke Abatement Society. Copies of *Smokeless Zones* may be obtained from the Society at Chandos House, Buckingham Gate, London, S.W.1, at 3d. each, post free.

CONGENITAL CHICKEN-POX

Infantile immunity to chicken-pox usually suffices to prevent an attack or it is negligible. Thus the disease is uncommon in the first year of life, but when it does occur may be accompanied by a profuse eruption, with marked constitutional disturbance. Intra-uterine transmission of the virus is rare. Only 9 cases have so far been recorded. They ran a fairly mild clinical course, with one exception, in which death occurred on the eleventh day of life. Oppenheimer[1] now adds a tenth case to this series by describing a congenital and fatal attack of chicken-pox in a coloured infant. The mother developed mild chicken-pox when seven months pregnant. A 4-lb. female infant was prematurely born five days after the appearance of the mother's rash. On the seventh day of life the infant developed a papulo-vesicular eruption which later became profuse, and on the eleventh day died with symptoms of respiratory distress. Any doubt about the true nature of the eruption was removed by the simultaneous development of chicken-pox in two hospital contacts fourteen days later. At necropsy, in addition to lesions on the skin, conjunctiva, and vagina, which had been noted during life, unusually widespread visceral lesions were found. These consisted essentially of zones of necrosis with typical intranuclear inclusion bodies in the oesophagus, stomach, intestines, lungs, liver, pancreas, adrenals, kidneys, thymus, and spleen. Focal necrosis alone was present also in the bone marrow of vertebrae and ribs. Examination of numerous brain sections revealed no abnormality. A detailed histological investigation showed there was a striking affinity of the virus for epithelial structures in the affected organs. Dermatropism in the chicken-pox virus is, of course, quite usual, but it is surprising that such an aggressive strain should have spared the nervous system. In contrast one of the very rare fatalities from chicken-pox in adult life[2] was characterized post mortem by disseminated lesions which included a diffuse encephalitis with areas of perivascular demyelination.

The Board of Trustees of the American Medical Association has cancelled the annual session for 1945, which was to have been held in Philadelphia from June 18 to 22.

In view of the continuing shortage of paper we must again ask authors to concentrate any articles they submit for publication and to cut out all verbiage. Every article longer than a memorandum should end with a brief summary.

Prof. F. Wood Jones, F.R.S., will deliver the Robert Jones Memorial Lecture entitled "Some Reflections on his Teaching of Myology" at the Royal College of Surgeons of England, Lincoln's Inn Fields, on Thursday, April 12, at 4 o'clock. Surg. Rear-Adml. G. Gordon-Taylor will deliver the Thomas Vicary Lecture entitled "The Medical and Surgical Aspects of the '45 (the Jacobite Rising of 1945)" at the College on Monday, April 16, at 4 o'clock.

THE EDUCATION OF MILITARY MEDICINE

ITS REFERENCE TO POST-WAR PLANNING

BY

ROBERT PLATT, M.D., F.R.C.P.

Brigadier; Consulting Physician, Southern Army, India;
Physician, Royal Infirmary, Sheffield

I have not felt justified so far in putting any record of my military experiences into print, for it has seemed to me that the gain was largely a personal one, communicable to others by advice at the bedside, but not original enough to warrant the writing of an article. It is true that one has become expert in the diagnosis and treatment of diseases which a few years ago one had never encountered, but that does not imply superior knowledge over those who have already written for many years on the subject of tropical medicine. At the present time, however, I feel that there are two reasons which justify a departure from my reticence; the first is that the experiences have now grown wide enough to be of some historical interest; the second is that in view of present-day discussions on post-war plans I feel the urge to present to those at home an outline of the life and work of a physician in the Army. I shall describe mainly my own experience, not because it has been unique or outstanding, but because it will serve as an example of the kind of work which most of us have been called upon to do.

My first posting was as officer in charge of the medical division of a military hospital in England. Here the work was at times dull and rather trivial, but nevertheless one went through what might be called a period of professional rejuvenation. One lived in a mess among colleagues from all medical schools. This led to an exchange of ideas which was most valuable. We held weekly clinical meetings in which the dermatologist and pathologist took part, and once a fortnight the Command neurologist came to spend a whole day reviewing every neurological case we had collected in the meantime. One worked, for the first time, in close touch with psychiatrists, and though serious disease and death were uncommon, one learnt much of disorders in their early stages. In exchange for the problem of advanced heart failure one had the more difficult problem of whether heart disease was present at all.

Such an experience is valuable for a matter of months but not indefinitely, and naturally our aim was to go abroad. My own hospital sailed for an unknown destination, which we rightly guessed to be North Africa, in Feb., 1943. We landed at Algiers, where unfortunately we were held up for a few weeks, but during that time I visited two hospitals already established, in both of which I found medical friends. I saw typhus for the first time, in the civil hospital, where Prof. Benhamou demonstrated rickettsia in the sternal marrow. We moved to Bône, where we set up a tented hospital for a few weeks; but the battle was moving on, and we followed it closely, opening up again at Medjes-el-Bab and then near Tunis. This brief period towards the end of the Tunisian Campaign was the only one in which my surgical colleagues were busier than I. Usually the medical division claimed two-thirds to three-quarters of the beds.

Mepacrine Intolerance

In April, 1943, the First Army began to take suppressive mepacrine (atebrin) in doses of 0.2 g. twice weekly, with almost disastrous results. Some complained of diarrhoea, vomiting, or abdominal discomfort after the first few doses; but after the fourth dose there was a widespread epidemic of diarrhoea and vomiting, choleraic in its severity, which in the worst cases was accompanied by pyrexia and prostration for 48 hours. It affected all units, to a varying extent, and though I am not in possession of all the official facts I know that it was not restricted to any one brand of mepacrine and that those who had the symptoms once had them again on returning even to a small dose of the drug, although they had taken the initial doses with impunity. Psychological factors were considered but ruled out. Later it was found that the affected individuals could be desensitized by the administration of small gradually increasing doses. The occurrence has never been repeated, so far as I know, in any other theatre of war, and the only conclusion was that the scheme of dosage with its intervals was an unfortunate choice and had led to sensitization.

Dysentery in Tunis

Just at the end of the campaign Flexner dysentery began to occur, at first sporadically, but later—fortunately just after the Cape Bon victory—as a major epidemic. All this time we were working as a forward hospital under improvised conditions, with no *x* rays, no sisters, and often only the most elementary laboratory facilities. Cases of dysentery kept pouring in, and more than half our staff succumbed. Although often acutely ill on admission, the cases on the whole were mild and soon recovered. There were no deaths.

We had continually to evacuate our patients, as soon as they were fit to travel, to hospitals further back, for beds were scarce and patients many. To admit 250 patients in a day, discharge or evacuate an equal number, and be working in primitive conditions in intense heat, pestered by flies, at the height of a Flexner epidemic adds to life's experiences. I tried an equivalent series of cases on sulphaguanidine, on fluids only plus a placebo, and on the traditional saline therapy (magnesium or sodium sulphate). There was no question that the sulphaguanidine cases did best; of the others in my series, "fluids only" achieved slightly better results than salines.

Malaria

In mid-June I was posted to a hospital in Philippeville which had sisters, *x*-ray department, laboratory, and every other facility. It was partly hutted and partly tented. For a fortnight we were relatively slack, but suddenly, on June 29, malaria appeared. Within a week or two I realized that I had probably seen more malaria than I had seen of, say, an ordinary condition such as auricular fibrillation, in my life—such is the suddenness of experience in tropical medicine. Nearly 50% of the cases were M.T., often in its worst form—a disease which can kill within hours. There will never be any agreement on the treatment of malaria, for it varies so much in severity from time to time and from place to place. I am convinced that most doctors in India, though long resident there, have not seen M.T. malaria as I have known it, in epidemic form among troops spending their first summer abroad. Fortunately our death rate was very small, though we lost one or two in our early days when the full significance and the symptomatology were not recognized. There was one man, for instance, who because of his symptoms was admitted to a dysentery ward. I did not see him until the next day, when he was breathless, pulseless, and collapsed. Rapid respirations are not sufficiently stressed as a common symptom of severe M.T.—a tachypnoea rather than a dyspnoea, more like an acidosis than pneumonia.

Our good results I ascribe unhesitatingly to the *extravagant* use of intravenous quinine; and to the usual indications for its administration we added one more—viz., "because it is night-time."

It was no exception to admit over 100 fresh cases every day, the majority arriving in the evening. Those who have worked in a tented hospital, where at night one sister supervises three or four wards, where neither sisters nor nursing orderlies have much knowledge of malaria, where the lighting is by hurricane lamps and all patients are under mosquito nets, will realize how easily a man might pass unnoticed into coma, and will understand why we preferred to give intravenous quinine at night to every patient who was really ill. Our dosage was 10 gr., repeated four-hourly if necessary, our vehicle 20 c.cm. of saline given slowly from a syringe. In over 500 intravenous injections we had only one death which could have been ascribed to treatment. That was in a German nursing orderly (in the P.O.W. compound) who was extremely nervous and apprehensive and died 10 minutes after the injection. One was reminded of the occasional deaths from pleural shock rather than of a drug idiosyncrasy. We never gave the dangerous intravenous doses of adrenaline still recommended in Manson-Bahr's *Tropical Diseases.*

We worked by day and by night in tropical heat, and if any member of my team reads this record I would like him to accept this expression of my gratitude for his devotion; for I have had officers of varying professional ability, but have yet to meet one who has been lazy or neglectful of his patients, despite the complete absence of any motive of gain, fee, or glory.

Other observations I might make on malaria are that whereas many of the M.T. cases relapsed early and were troublesome until Christmas, all the late relapses in the following spring and early summer were B.T. We saw M.T. in all its forms—the cerebral, the algid, and the dysenteric; as a cause of anaemia, of nephritis, even of ascites. Blackwater fever was not encountered.

Smallpox and Diphtheria

All the time we had, of course, our infectious wards and our skin wards, and we learnt, among other things, the differential diagnosis of early smallpox. Later in the year we had diphtheria, both cutaneous from so-called desert sores and faucial. At one time we had 140 diphtheria cases in hospital. Peripheral neuritis was common. Infective hepatitis was our biggest disabling disease in the autumn and winter, but I have no new observations to make upon it. Other infections we had in smaller numbers—chickenpox, mumps, typhoid, and glandular fever. We did Paul-Bunnell tests whenever our pathologist could catch a sheep. Typhus was almost unknown among the troops.

Italy

In Jan., 1944, we had a month's rest while waiting to cross over to Europe, and during that month I found time to read more medicine than I had read for many years. Although we may be divorced from the larger library facilities where exasperating references can be patiently sought out, there is always plenty to read in a general hospital. The Army provides a number of textbooks and a fund for buying more, and almost every officer has brought a few of his own, so that by lending or pooling there is no shortage of monographs and reference books.

We reached Naples in February, towards the end of the typhus epidemic which had broken out in the civil population. The weather was bitterly cold and there was no fuel or transport. Air-raid damage was considerable, and it was no wonder that lice and typhus spread among the half-starved half-frozen population, huddled together as they were in conditions of squalor I have seen in no other European town. Adults and children would steal and eat the food from our swillbins. The epidemic has made history, for it ceased abruptly when the populace was deloused on a grand scale by D.D.T. Dusting centres were set up in all parts of the town, propaganda was used to bring the people to them, and hundreds of thousands of persons were disinfested. Venereal disease was the greatest scourge of Naples, and the town was banned to all troops not actually stationed within its boundaries.

For a time we were employed as the evacuation hospital for Italy, and we saw every interesting long-term case on its way home—heart disease, neurological cases, nephritis, hypertension, lung abscess, occasional neoplasms, and anaemias. Our clinical meetings were as well off for material as those of most teaching hospitals, and were attended by many of the M.O.s in the district, including some from the Navy. We saw kala-azar for the first time, often in troops who had come direct to Italy from the U.K. Amoebic dysentery became a major problem, B.T. malaria was still with us, and a sharp epidemic of sandfly fever broke out.

From Naples I went to Rome, where much the same diseases occurred, with rather more typhoid fever than I had seen before.

India

From Rome to India, where a somewhat new outlook is required, although the main diseases are the same. One meets a case of foot-drop, for instance, and thinks not of lead poisoning but of leprosy. A severe pneumonia or adenitis arouses suspicions of plague. In West African troops we see trypanosomiasis, schistosomiasis, and yaws. The ancylostoma is ubiquitous, and nutritional anaemias and deficiency states are abundant. Sprue adds an enigmatic interest. Relapses of B.T. malaria, mild but repeated, cause our biggest loss of man-power, and amoebic dysentery is widespread.

Non-tropical Diseases

Of the non-tropical diseases we always have a plentiful supply. Chests of all kinds we see frequently, gastrics, psychoneurotics, anaemias, early heart cases. Pulmonary tuberculosis we meet far more often than we do at home, where all such cases are segregated in sanatoria.

Here, in the Southern Army, we have a first-class neurological centre where every variety of disorder can be demonstrated. In conjunction are the neurosurgical centre and peripheral-nerve-injury department, and there is an expert neuropathologist. We have hospitals set aside for tuberculosis, where collapse therapy of all kinds is carried out on suitable cases. We have research teams in dysentery, anaemia, malaria, and other subjects. Tropical eosinophilia and arsenical encephalopathy are interesting us; poliomyelitis is all too common. Opportunities for teaching are of everyday occurrence. Clinical meetings are held regularly in all big hospitals; the M.R.C.P. examination has been held in India and the Middle East. In my present post I have an ideal opportunity of meeting and discussing medicine with physicians representing every medical school in Britain and in India. I never leave their hospitals without having learnt something from them.

General Education

I have written enough now to achieve my object, which is to show that the physician abroad will come home rich in experience. He may be a trifle rusty on globin-insulin and thiouracil, or the management of the enlarged prostate, but these subjects he will relearn as quickly as he has applied himself to the problems of military medicine. Meanwhile his general education has not been neglected. If he has the aptitude he may now read or speak with some competence in four or five languages; he may have studied history in Constantine, Carthage, Baghdad, and Delhi; or architecture in Rome, Pompeii, and Agra. He may have listened to Italian opera and seen the Sistine Chapel. At a time when we are out to encourage better general education in our profession such experiences cannot be dismissed as irrelevant. Hospital planning and administration too have come his way, and, above all, the study of human nature in its many aspects, among different races and conditions, in heat and strain and danger. Personality has developed with the command of men. I speak not only for the physicians whom I know at first hand but also for others who have had like experiences and will return the better for them.

After the War

I admit to a touch of propaganda in my discourse. It is not for the benefit of the older ones like myself, established in their jobs at home, but because at this period of the war I hear frequent questions as to what will happen afterwards: "Will the jobs be filled before I get home?"; "Will partial demobilization mean that the late-comers get no chance, that posts are occupied before Japan is beaten?"

I feel that those at home are losing patience. I know that they have every excuse. They have worked hard and long, waiting for our return. They also are getting older. But we out here are *not allowed* to be impatient. We have to take what comes and go where we are sent, for as long as we are required, without question, without choice.

Many of the physicians in the Army have jobs to return to, but the younger ones have missed the opportunity of the appointment which leads to a career in medicine. They have been away already for five years. Those at home must be patient a little longer. The jobs must not be prematurely filled. Moreover, if we are to attract the best men we must realize that they are already ripe in years. The man who at 28 would gladly have accepted a post at a small salary if it offered chances of advancement, cannot at 34, with a wife and child, afford to do so. Unless teaching schools offer adequate remuneration over the lean years many of these men will take whole-time salaried posts in other branches of medicine or will go into general practice.

Physicians in the Services are not asking favours of the profession. They do not expect equality of sacrifice, but they have a right to equality of opportunity. All posts filled in wartime should be temporary in the strictest sense. However difficult it may be, they should be vacated without question when the war with Germany and Japan is over. Then there will be open competition in which those who stayed at home will get an equal but not an unfair chance.

I have not the slightest doubt that, given the opportunity, many of our younger physicians in the Services will then come to fill with credit some of the best posts we have to offer, and they will bring with them a wisdom which textbooks do not teach.

DISTRIBUTION OF PENICILLIN

A circular from the Ministry of Health says that increasing supplies of penicillin are now becoming available for the treatment of civilian patients and the Minister is anxious that it should be more widely used in suitable cases. It has not yet been possible for it to be placed on the market freely through commercial channels, and some degree of control in its use is still essential. Hitherto supplies for civilian patients have been distributed through the university medical schools and the teaching hospitals, but the Minister wishes to relieve these bodies so far as possible of the detailed responsibility for control. It has been decided therefore to increase the number of distributing hospitals or centres and to revise the "Recommendations of Conditions to be Treated."

Functions of Distributing Centres

The distributing centres have been chosen, in consultation with the university medical schools, from among the hospitals, both voluntary and municipal, which have adequate laboratory facilities and have had experience in the use of penicillin, regard being had to their geographical position in relation to the main centres of population.

For the present the issue of penicillin will be free of charge. While detailed returns of the types of cases treated will not be required, records of consumption and of distribution to other hospitals, etc., with receipts for quantities so supplied, should be kept and made available for inspection by an officer of the Department.

Each distributing centre would receive supplies of penicillin direct and in turn would distribute an immediate supply to the hospitals in its neighbourhood which have laboratory facilities and experience in using penicillin. Other hospitals in the area would be entitled to receive penicillin on application for the treatment of suitable cases. Each distributing centre would further be authorized to issue penicillin to private practitioners for the treatment of suitable cases at home or in a nursing home whom it is not practicable to transfer to hospital. It is suggested that the distributing centre should form a small medical committee to be responsible for the further distribution and to give advice in doubtful cases.

The Minister has in view the desirability of at least doubling the use of penicillin in the course of the next two months with progressive increase, and it is suggested that an immediate issue of 2 m.u. per month for every 100 beds for patients with acute diseases should be made. Further supplies in excess of this amount will be available as required on application to the Ministry. It is understood, however, that the university medical schools have a substantial reserve of penicillin for civilian cases, and if a further supply is urgently required in emergency application should be made to the nearest university medical school. Present arrangements for the supply of penicillin for Service patients will continue.

Syphilis and gonorrhoea have been transferred to the list of conditions which may be treated in suitable cases, and it is anticipated that increasing use will be made of the drug for these purposes. It is intended that the V.D. clinics attached to the several hospitals will have supplies allotted to them from the distributing centre.

Revised instructions on the indications for the use of penicillin, and methods of administration, are enclosed with the circular for distribution to the local hospitals.

Owing to staff difficulties the manufacturers will have to "stagger" the dispatch of penicillin, and different hospitals will receive their supplies on different dates in the month. Any hospital needing penicillin before the initial distribution arrives should apply to the appropriate university medical school. Hospitals which have supplies of penicillin for Service cases may borrow for the treatment of civilians until the arrival of the first quota.

E. L. Cohen (*Brit. J. Derm. Syph.*, 1945, **57**, 10) examined the incidence of acne in a group of 500 women and found that the maximum age incidence was 19 to 21, but that acne was still common in the late twenties and early thirties. In a group of 207 men in whom acne was found the largest age group was 18 to 23, but 25% were over the age of 25. The distribution in a group of women showed that acne was commoner on the trunk than elsewhere.

Reports of Societies

MASKING EFFECT OF SULPHONAMIDES IN OTITIS MEDIA

The masking effect of sulphonamides when used in the treatment of acute otitis media was the subject of discussion in the Section of Otology, Royal Society of Medicine, on March 2. Mr. L. GRAHAM BROWN, president of the Section, was in the chair.

The subject was introduced by Mr. I. MALCOLM FARQUHARSON, who presented a statistical comparison of 1,194 cases of acute otitis media treated in pre-sulphonamide days from 1932 to 1936 with 1,390 cases treated with a sulphonamide from 1937 to 1943. The cases requiring mastoidectomy in the pre-sulphonamide group amounted to 29%, and in the sulphonamide group to 13%, but he said that sulphonamides masked certain signs and symptoms of mastoiditis by permitting a latent course of infection. By delaying drainage the masking effect was increased, and the instances of deafness and chronic ear disease were multiplied. The pathological processes of acute infection of the middle ear and mastoid were altered by sulphonamides, giving rise to a "mottled" distribution of the disease, with special affinity for the dural plate. There was an accumulation of evidence to show that sulphonamides altered the translucency of the mastoid cells to *x* rays.

Mr. G. EWART MARTIN said that nowadays a large number of cases were treated outside the hospital by private doctors, and it was among these cases that eventual deafness appeared. A typical case was that of the person who came to hospital with a history of acute ear; he had seen his own doctor and had been given "a box of pills," possibly sulphathiazole, and had been told to take two thrice a day. Later the doctor had seen him and pronounced him well, but about three weeks later he came to hospital complaining of severe deafness. On the other hand, among private cases, which were usually seen quite early by the otologist, persisting deafness was infrequent. The trouble was the indiscriminate use of sulphonamides by some general practitioners, who had found that when they were given the temperature went down and the pain ceased; but deafness often resulted.

Squad. Ldr. G. H. BATEMAN said that he had been through a number of case histories in the R.A.F., and had figures which suggested, unlike Mr. Farquharson's, that the use of sulphonamides had increased the number of mastoid operations carried out. Of two groups of patients, one treated with sulphonamides and the other not, those in the first group had had more mastoid operations; but the statistician to whom he showed the figures declared that statistically they were not valid. His own feeling was that acute otitis media was not beneficially influenced by sulphonamides, but that with sulphonamide in the background expectant treatment was adopted to a greater extent than in the pre-sulphonamide era, and therefore better results were obtained.

Mr. A. R. DINGLEY agreed that in pre-sulphonamide days it was usual to open the mastoid rather earlier than was now the rule. The emphasis on the possible injury to hearing was important. The trouble was due to the fact that these drugs were often expected to take the place of necessary surgical drainage. After other signs had cleared up the ear drum might be found to be oedematous, and there might be a marked degree of deafness. Such an ear was potentially dangerous.

Squad. Ldr. DICKSON said that in the Services it was the rule to get cases of acute otitis media as early as possible into hospital and to advise medical officers that they should wait until the patient was in hospital before giving sulphonamides. Thus the cases were under the observation of an otologist from the moment the drug was begun.

Mr. TERENCE CAWTHORNE said that such a discussion could be satisfactorily concluded only if a series of cases were treated without sulphonamides and a corresponding series with sulphonamides. One other aspect of the use of sulphonamides which might prove important was the likelihood of some patients, on feeling sick after one or two doses, refusing to continue the treatment.

Mr. Owen pointed out that in civil life early treatment of these cases in hospital was impossible unless otitis media was made a notifiable disease. An authoritative statement ought to be forthcoming advising practitioners as to the use or non-use of sulphonamides in the early stages. Mr. Wilson said that he was now operating on far more mastoids than he had ever done before, and this he attributed partly to the giving of sulphonamides. He also urged that a small committee of investigation should be formed with a view to correlating treatment and issuing a statement. Mr. Thacker Neville said that family doctors in his area were treating ear cases with sulphadiazine, and therefore the otologist did not see them, and the ears were never inflated after the inflammation had subsided. The want of such inflation, he thought, was partly the cause of deafness. Mr. H. V. Forster mentioned the comparative insolubility of sulphadiazine, which on some grounds might be preferred to the other compounds. He urged that if the drug was given potassium citrate should be prescribed and plenty of fluid.

Mr. Ritchie Rodger said that the problem was a physical as well as a chemical one, and chemotherapy was of no use on the physical side of the problem. The first symptom that brought the patient to the doctor was earache, which was nearly always due to tension. With these new drugs the symptoms were suppressed, and the physical side of the problem was not dealt with, so that deafness from an adhesive process in the middle ear might result. It should be explained to general practitioners that the middle ear did not respond to these drugs in the same way as the lungs and the meninges because in the ear there was not the very efficient drainage which Nature had provided for serum in the brain and in the lung. Major Houple, U.S.A.M.C., mentioned a case of mastoiditis which, masked by penicillin, went on to brain abscess.

Mr. Graham Brown said that they had all had examples of these cases in which masking had occurred, and could come to the conclusion that a sulphonamide had been administered, perhaps unwisely. In hospital and even in private practice very few cases of acute otorrhoea came early enough to permit of treatment with a sulphonamide. Certain unhappy results which he had seen had made him rather disinclined to use sulphonamides, though he did recognize their value, particularly in complications.

Mr. Farquharson, in reply, said that even with adequate dosage of the drug certain masking effects might persist. The opinion of the meeting was evidently against the promiscuous use of the drug. Squad. Ldr. Bateman had said that mastoid operations had been more frequent since the drugs came into use; this was not borne out by his own records. He did not think that resulting deafness was due, as Mr. Thacker Neville had suggested, to lack of subsequent inflation. As for masking by penicillin, it was conceivable that this could occur in the same way as with a sulphonamide. The masking in otitis media was very largely due to the drug not reaching the mastoid owing to thrombosis of the vessels, and that might equally occur with penicillin.

INFECTIONS OF THE EYES

At a meeting of the Fever Group of the Society of Medical Officers of Health on March 9, Dr. M. Mitman presiding, a discussion on the epidemiology and treatment of some eye infections was opened by Prof. Arnold Sorsby. He said that a provisional analysis of 9,622 certificates of blindness in the L.C.C. and Middlesex areas showed that 1,427 persons (or 15%) were blinded by infectious diseases. In approximately three-quarters of this 15% ophthalmia neonatorum and syphilis were the responsible factors, ophthalmia neonatorum being the cause in 265 cases, congenital syphilis in 516, and acquired syphilis in 290 cases. The remainder of the 15% was contributed largely by trachoma (134 cases) and the various specific fevers (103 cases). The low incidence of infectious disease among the causes of blindness in England and Wales was in striking contrast to the conditions obtaining in countries like Egypt and in the Middle East generally, where over 80% of all cases of blindness were caused mainly by the acute ophthalmias, and to a lesser extent by trachoma. At one time, however, infection was the major cause of blindness in England. At the beginning of the last century smallpox was the largest single factor, and towards the end of the century ophthalmia neonatorum. Even as late as 1922 ophthalmia neonatorum was the cause of blindness in some 30% of all children at blind schools; by 1942 the incidence had fallen to about 10%. This decline had shifted the emphasis from infection to other factors—genetic anomalies in the young and degenerative lesions in the elderly.

Though the incidence of blindness from ophthalmia neonatorum had fallen so markedly, there was no evidence that the disease itself had declined to any extent. A clearer appreciation of the aetiology of ophthalmia neonatorum was needed, particularly as it had now been established that only some 20 to 25% of cases were gonococcal in origin. At least 10% of cases were due to virus infection, and the aetiology of this and other types needed clearer recognition. While congenital syphilis had also declined to a gratifying extent, other transmitted maternal infections were only now being recognized, toxoplasmic choroido-retinitis being an example. The decline in the incidence of trachoma in childhood had only emphasized that there was still a considerable residue of trachoma in the adult population, and these people constituted a possible source of epidemic outbreaks.

The sulphonamides and penicillin were of great help in the treatment and elimination of infectious eye disease. Ophthalmia neonatorum was now easily controlled by the oral administration of the sulphonamides and the local application of penicillin. The acute ophthalmias of tropical and subtropical countries also responded well to the sulphonamides, while in trachoma local application of the latter had rendered the classical methods obsolete. These new drugs were, however, likely to be effective only in the bacterial infections of the outer eye. Intraocular inflammation was rarely bacterial in origin, and such common conditions as iritis and choroiditis still needed intensive study.

In reply to questions Prof. Sorsby said that it was doubtful whether the routine prophylactic use of silver had made any major contribution to reducing the incidence of ophthalmia neonatorum, nor did he think the sulphonamides would be likely to do so. Routine instillation of penicillin eye drops at birth deserved extended trial when supplies became more plentiful. The placenta was a powerful barrier to the transmission of intra-uterine infections, and it remained uncertain which organisms could pass. Much of what had been called intra-uterine inflammation was really genetic disease. This required much closer study from the medical profession than it had received in the past. There was, nevertheless, a considerable field for the study of transmissible intra-uterine infections.

The Joint Tuberculosis Council, which met in London on Feb. 17, re-elected Dr. James Watt as chairman, Drs. D. P. Sutherland and N. Tattersall as vice-chairmen, Dr. A. P. Ford as honorary treasurer, and Dr. Norman England as honorary secretary. The Council adopted a resolution recording its deep sense of loss at the death of Sir Henry Gauvain, its chairman 1926–9. It was decided to ask the British Medical Association to receive a deputation representative of the Joint Tuberculosis Council and the Tuberculosis Association on the need for a national campaign for a safe milk supply. The National Association for Prevention of Tuberculosis was invited to join in the deputation. Dr. G. Jessel reported that ten memoranda on tuberculosis subjects had been prepared for publication for U.N.R.R.A. The memoranda would form a manual for distribution to medical practitioners and others dealing with tuberculosis problems in occupied countries after liberation, and 1,000 copies of the manual would be distributed to tuberculosis workers in Britain by the Ministry of Health. The subjects covered by the memoranda included administration, dispensary and sanatorium treatment, rehabilitation, bacteriological diagnosis, differential diagnosis, mass radiography, surgical treatment, non-pulmonary tuberculosis, and tuberculosis in childhood. Approval in principle was given to a proposal submitted by the Committee on Education (jointly set up with the N.A.P.T.) for the establishment of a Tuberculosis Educational Institute.

The British Orthopaedic Association has elected the following Honorary Members: Sir Alfred Webb-Johnson, Bt., P.R.C.S., Prof. R. I. Harris, Toronto, Prof. N. N. Priorov, Moscow, and Mr. J. Rhaiadr Jones. It has also elected two Corresponding Members: Prof. Sten Friberg, Stockholm, and Dr. A. P. Kotov, Kharkov.

Correspondence

Women in Labour

Sir,—Nearly one hundred years ago Simpson failed in his attempt to give relief to all women in labour because his contemporaries and his successors did not try to understand Simpson's teaching, and they never mastered the technique of chloroform analgesia in labour. It looks very much as if a very safe and simple method known as gas-and-air analgesia might meet with a similar fate, not because patients are being killed by gas and air, but because of unsatisfactory analgesia resulting from unsatisfactory administration.

I know that at least 80% of all patients should get adequate relief of pain from gas if due and proper attention is paid to the details of administration, yet I am satisfied from my own observations that all over the country, in hospitals and in homes, this attention to detail is not forthcoming. I have seen machines out of order, gas cylinders empty, facepieces that do not and could not fit the patient's face, and, in fact, both apparatus and technique of administration which could not be expected to give analgesia. I have found that there is also complete failure to instruct the patients how the gas should be used and to see that the administration is started sufficiently early in labour. So often I find patients, well advanced in the second stage of labour, rushed into the labour ward, given the facepiece of the machine (which they have no idea how to use), and then just told to "get on with it." This slackness and indifference to the suffering of women are deplorable features of our national life to-day.

In 1939 we were making very real progress in our attempts to relieve all women from the pains and misery of labour, but during the last five years there has been a wave of shallowness and insincerity passing over our land. I can only hope that when this war is over our young people returning from the Services will bring with them into our daily life a new spirit of service and duty towards their fellows. That this spirit of service is needed there can be no possible doubt. Following an article in the *Nursing Mirror*, I received letters from women in all parts of this country. These letters all told the same sad story—a story of indifference and neglect, a story of avoidable suffering and misery, which must make us utterly ashamed of our national maternity services. How are we going to explain away this indifference and neglect of the sufferings of their young wives to our returning soldiers, sailors, and airmen? Truly our maternity services leave much to be desired.

From gas-and-air analgesia, and more recently from trilene-and-air analgesia, we can, without any possible doubt, promise a very high degree of relief from the pain and misery of labour. Yet we are doing so little, so very little. Are we to say to returning warriors who have endured so much: "Oh, yes, we can help your young wife tremendously, but really it is too much trouble, so we are not going to bother." Has then the work of our women in this war been of no account that we must allow this deplorable state of things to continue?

One strange fact I have noticed. Our strongest supporters in our attempts to obtain analgesia in labour for all women have been old and elderly male county councillors; our strongest opponents, young women medical officers of health. Perhaps there is going to be a place in our post-war world for the old men after all that has been said about "youth at the helm."—I am, etc.,

New Barnet. John Elam.

Ovariotomy or Caesarean Section?

Sir,—In a perfect world with perfect antenatal supervision all ovarian cysts will be diagnosed in early pregnancy and removed. On the one occasion when I was forced to remove a cyst during the second stage, the membranes having ruptured 24 hours previously, I had the greatest difficulty in getting the uterus back into the abdomen. Had not the risk of sepsis been present I should certainly have performed Caesarean section.—I am, etc.,

London, W.1. Malcolm Donaldson.

A Faculty of Ophthalmologists

Sir,—The letter of Dr. C. R. Duncan Leeds (March 3, p. 311) is likely to create a false impression. There is no question of increasing the number of ophthalmological organizations, since the Council of British Ophthalmologists will cease to exist as such on the inception of the Faculty. Indeed, if, as is desired, a certain union takes place, the number will be reduced to two—the Faculty and the Ophthalmic Group Committee.

The establishment of two kinds of members appeared to be inevitable, but the Faculty certainly hopes to be in a position to promote the interests of the younger men. The promoters did not view with favour the perpetuation of the "part-time ophthalmologist," who will, however, continue to be adequately represented by the Ophthalmic Group Committee. The closest liaison between the Faculty and other representative bodies such as this is earnestly hoped for and anticipated.

The Council of British Ophthalmologists does not consider that "much help in the proposed National Health Service" will be required from part-time ophthalmologists, and the scheme which the council has envisaged will, it is hoped, ultimately function without them. One readily agrees with Dr. Leeds that, in the interim, "the Ophthalmic Group Committee is best constituted to be their guardian angel."—I am, etc.,

45, Lincoln's Inn Fields, London, W.C.2. Frank W. Law,
Hon. Secretary, C.B.O.

Artificial Respiration

Sir,—The letter from the Royal Life Saving Society (March 17, p. 387) shows that I was unable to convince them at my 1944 demonstration that the rocking method of resuscitation is more effective than Schäfer's. I had hoped to convince them (by subsequent x-ray photographs) that when the toneless diaphragm had been pushed up by Schäfer compression it did not recoil down again elastically but stayed put, thereby making Schäfer's method impotent in advanced asphyxia. But unexpected difficulties have so far prevented Dr. Din and myself from demonstrating this by x rays. However, there is other evidence for this doctrine, such as the following.

1. When one side of the diaphragm is deprived of its tone by cutting the phrenic nerve its dome rises at least two inches.

2. In the rocking method the weight of the abdominal contents pushes and pulls the flaccid diaphragm up and down like a piston. Dr. J. E. Bannen showed this by a portable x-ray in my original case of diphtheritic paralysis of the diaphragm.

3. Dr. H. W. Haggard, the U.S.A. expert in respiration, was at hand when a man died suddenly of cardiac failure. He promptly started Schäfer's method, which ventilated the lungs normally at first but failed completely to do so after 10 to 15 minutes. Presumably the toneless diaphragm had been pushed up and stayed there: the elastic recoil, on which Schäfer's method relies for inspiration, was absent. This view was confirmed when an overdose of chloroform was given to a cat till respiration ceased. Schäfer's compression produced normal ventilation (measured) at first, but this ceased after 10 minutes and the lungs were found to be collapsed. Prof. R. R. Macintosh in 1944 simulated the condition of a drowning man by ether anaesthesia of two volunteers with periods of apnoea induced by hyperpnoea. Results in the two subjects were: for Schäfer 340 and 530 c.cm.; for Silvester 400 and 650 c.cm.; by rocking 580 and 860 c.cm. Results of artificial respiration in conscious subjects are notoriously misleading, but the above tests are conclusively in favour of rocking over Schäfer as regards ventilation of the lungs.

4. The intricate experiments of Prof. Hemingway in 1944 showed the definite superiority of rocking over Schäfer's method in aiding the circulation. This is most important, for it is useless to oxygenate blood by pumping the lungs if it is not propelled to the respiratory nerve cells which maintain respiration (and to the heart muscle).

5. Finally, there are the very many instances of the failure of Schäfer's method, and, in particular, the lack of inspiratory recoil such as was observed by Surg. Lieut.-Cmdr. Gibbens. This led him and Surg. Lieut. de Launay to adapt the rocking method to naval usage and to its later official description in *First Aid in the R.N., 1943,* advocating that it replace Schäfer's method whenever possible. I am permitted to state that the

proportion of successful resuscitation in the Royal Navy since rocking has been used has increased.

I can claim to have no bias against Schäfer's method because in a booklet by me on artificial respiration (soon to be published) it is recommended for use in adults when the rescuer is single-handed. But it fails much oftener than it succeeds, and we must strive for better methods to save the failures. It is not fair or right to expect a society of philanthropic laymen to pronounce judgment on rival methods of resuscitation—a subject which has now become highly complicated. What is needed is a small expert subcommittee of perhaps the Medical Research Council, not only for research but to give official sanction that certain methods deserve to be tried out by the societies which instruct first-aiders, who should also be asked to suggest practical improvements. Advances will come only by the co-operation of doctors, first-aiders, and laboratories.—I am, etc.,

FRANK C. EVE.

Penicillin in Bacterial Endocarditis

SIR,—Since the announcement made in these columns (Feb. 17, p. 232) of the formation of ten centres to investigate the value of penicillin in the treatment of bacterial endocarditis, three further research centres have been formed in Newcastle, Birmingham, and Glasgow. Physicians are invited to refer patients suffering from subacute bacterial endocarditis to: Prof. F. J. Nattrass, Royal Victoria Infirmary, Newcastle-upon-Tyne; Prof. K. D. Wilkinson, Queen Elizabeth Hospital, Edgbaston, Birmingham; Prof. J. W. McNee, or Dr. W. R. Snodgrass, Western Infirmary, Glasgow.—I am, etc.,

RONALD V. CHRISTIE.

Shock Therapy and Conditioned Reflexes

SIR,—Relative to Prof. R. J. A. Berry's letter (March 17, p. 383), I would like to join issue with him on certain points. Like the great "reflexologist" Pavlov himself, your correspondent disregards the fact that determining the formation of any conditioned reflex is the anticipatory fulfilment of a wish—a wish, that is, for pleasurable gratification or the relief of instinctual tension. In his concern with the cortical associational system, which closely parallels Freud's second psychic instance or the reality principle (see Freud's *Interpretation of Dreams*), Pavlov leaves out of account anything equivalent to Freud's basic and therefore most important first psychic instance, better known as the pleasure principle. Though with supplements and modifications later in life, Pavlov earlier denied that behaviour was to be regarded as purposive—i.e., the fulfilment of a need—and, according to Frolov, one of his pupils, at one time even went so far as to impose fines upon any of his assistants who dared demur. Nevertheless, the inescapable truth remains that there can be no anticipatory gratification, no conditioned reflex, and no continuance of such as may already have been formed once newer engrams have had time to develop, recording repeated failure of realization of the looked-for gratification—e.g., food—unless these latter have themselves somehow been modified or destroyed. These newly formed inhibitory engrams also serve indirectly the pleasure principle by the avoidance of pain (disappointment).

Upon a basis of experience the animal has learned to avoid expectancy, and since their formation is based upon actual external experience, these newer engrams also serve the reality principle. What your correspondent euphemistically refers to as the "recall" properties of shock therapy are, in my view, merely the "inhibition of an inhibition," and amount to an actual loss of judgment occasioned by electroconvulsive therapy (E.C.T.). The valuable new engram which represents the enlightenment of further experience has been deleted thereby, and the animal's capacity for adjustment to reality temporarily diminished. When so viewed, this, while perhaps less a matter for enthusiasm, is an observation no less important when cleared of positive misunderstanding. Incidentally I would suggest that the same significance attaches to Gellhorn's interesting observations upon the effects of insulin as a restorative of the conditioned reflex reported in your annotation (Feb. 10, p. 191). In both cases when properly assessed the apparent gain is clearly a loss from the point of view of the efficiency and aptitude of the animal's performance—i.e., it behaves less intelligently. This conclusion suggests that so far as conditioned reflexes are concerned, both E.C.T. and insulin operate by detraction and not by addition—a point of some importance. That many undesirable though later-acquired inhibitive tendencies exist among the psychopathological formations of man and can with advantage be removed is a corollary which seems reasonably to follow.

To return, leaving this digression, it is for the reasons above stated that these purely neuronic conceptions, whether of dreams, the vagaries of memory, or of Pavlov's conditioned reflexes, lose much of their validity, inasmuch as they omit entirely the essentially affective basis of animal activity upon which all that follows in the neuronic associational sphere is but a modifying superstructure. From the evolutionary point of view the higher organic nervous system, or neopallium, is but a refinement of recent development. Living organisms possessing the rudiments of mind long preceded that development, but the gratification of instinctual needs has never been replaced and still holds unquestionable priority as the determinant of animal behaviour, including, of course, man.—I am, etc.,

Warlingham Park Hospital. WM. H. SHEPLEY.

Deaf Aids

SIR,—I have seen the correspondence on the subject of deaf aids which has appeared in your *Journal*. I have been deaf since 1916 with middle-ear deafness, and having led an active business life since, which would have been impossible without the use of hearing aids, my experiences do support the statement that considerable sums must be set aside yearly for the upkeep of these. My expenditure has been over £50 a year, but I have had some twenty sets.

I am a member of some six technical societies—I have in fact been chairman of the Regional Sections of the Royal Institute of Chemistry and the Society of Chemical Industry—further, I have been upon a number of technical committees meeting in London, Leeds, and elsewhere, for which much travel has been necessary. Thus, I usually take two portable sets, of which I have five, in case one should break down. The portable sets do not "travel" well and a knock on a suitcase in the corridor of a train has been sufficient to break a valve. I have two all-mains sets in my offices and one at my home; I sometimes use one of these in London at meetings providing I know beforehand that a convenient connexion is available. I carried a portable set strapped to my belt as a Home Guard dispatch rider, but this proved too costly owing to breakages.

Service has sometimes taken months. I have always had sympathetic treatment from the manufacturers, but they are in turn dependent upon various makers of accessories who are not sympathetic. Apart from the time of servicing, transport is a problem. Twice I have had sets smashed in the post. Many incidentals in the upkeep of these aids are forgotten: e.g., telephones lose their sensitiveness eventually—especially those of the bijou type—and I have four away for servicing with little hope of repair or renewal.

Dr. Littler has done great work in describing simple aids, but it must be realized that deaf people are not necessarily mechanically minded enough to build or repair sets. Although a crystal microphone can doubtless be readily made into an amplifier, my experience in building sets to circuits issued by firms making components has not been happy, even though I have a laboratory at my disposal. If professionals are asked to do this the cost is likely to be high. As it is I will not allow an amateur to service a set because once I had a set so "pied up" that the manufacturer refused to handle it afterwards.

My experience with batteries of the most reputable brands has been good but the supply has been bad, despite the promises made in the House. The cycle-lamp type has given usually an hour's good life. After rest periods their activity lasts for periods which follow a logarithmic decrement. Rarely have I had less than two months' life from the bijou high-tension battery. What is less understood is that a low-tension battery very soon loses enough energy to activate an amplifier, though it still has ample power to work a flash-lamp, and batteries which have a considerable amount of energy have to be scrapped. I attended some meetings in London last week and half used up six low-tension batteries. Two others of unknown make I bought from a shop in Westminster were worthless although they were satisfactory by the usual shop-counter test —one lasted two minutes. Despite the fact that in my home and office I am independent of portable aids, yet I spend some 5s. a week on batteries for portable sets.

One great service which could be done for deaf people is for some influential person to claim income-tax rebate on the expenditure incurred in the maintenance of these aids, get it, and so establish the precedent. Such expenses are "necessarily incurred in the execution of one's business," for without them it would be impossible to earn. Although it is obvious I should be able to pay little or no income tax without the aids, yet the Income Tax authorities do not accept the plain implication of their own definition of expenses. I hope the publicity which has appeared in your *Journal* will help to change this view, since a sum of £25 per annum will hardly cover the expenses of a user of deaf aids who has to carry these about in the course of his duties, and this is a considerable sum for those who naturally find it difficult to compete in the labour market. I speak of those whose deafness is such that the simple one-battery-transformer aid will not suffice. In fact I believe, from intimate knowledge of many deaf people, that when the degree of deafness is such that an aid must be used the simple type is of little value and valve aids must be sought.

I apologize for the length of the letter, but this matter is of especial interest to those deafened in the last war—and this.—I am, etc.,

A. H. Dodd, M.A., F.R.I.C.,
Chief Chemist, Thorncliffe Works, near Sheffield

Injection of Solvochin

Sir,—Dr. Frank Hawking's report (March 24, p. 412) must be of great interest to all who have used solvochin, but there is a danger that others, who have no practical experience with it, may draw the conclusion that the injections are either painful or harmful. In practice intragluteal injections of solvochin, properly given, are very well tolerated, and an experience extending over a period of 3 years and more than 100 cases has shown that complications must be very rare. In the treatment of malaria I have used 8 injections spread over 4 days and there have been practically no complaints of pain. This is in striking contrast to my experience in liver therapy in tropical sprue. Local necrosis is probably unavoidable when quinine is injected, but should not be allowed to influence us against using a preparation which is clinically efficient, economizes quinine, ensures certainty of administration, and is so well tolerated by patients.—I am, etc.,

London, W.1. Alec Wingfield.

Blackwater Fever and Malaria

Sir,—In the *Journal* of March 10 (pp. 325 and 328) are two papers, "Blackwater Fever in West Africa," by Lieut.-Col. E. W. Skipper and Capt. G. L. Haine, and "Diagnosis of Malaria in West Africa," by Squad. Ldr. D. G. Ferriman. Skipper and Haine mention the "characteristic slow pulse of malaria." Characteristically, the pulse of malaria seemed to me rapid in comparison with sandfly and typhoid. Again, they write: "Preceding and during the disease [blackwater] parasites are scanty in the peripheral circulation, often disappearing entirely early in the illness." This observation agrees with general experience. Later they state: "We consider it [alkali] should be used as early as possible—in fact, the urine of all our cases of malaria was kept alkaline as a routine." Sinton has urged this routine since about 1908 in India. The authors' further recommendation that "protein should be restricted until well into convalescence" is open to question in view of recent work.

Squad. Ldr. Ferriman approves of the therapeutic test in doubtful cases of malaria. The therapeutic test is valuable if certain conditions are observed. A distinguished colleague of mine, whose professional skill I greatly admire and respect, once asked me to see a case of "? malaria with early jaundice and slipping into coma." This patient had *falciparum* malaria —proved by blood film—and had received 30 gr. of quinine a day for five days. I went with my friend to see the patient, who was indeed very ill. My colleague thought the patient could not possibly have malaria and that my laboratory technician had been mistaken in his examination of the blood film. I asked for a specimen of the patient's urine. This was provided and we tested it with Tanret's reagent: *there was no quinine in this patient's urine.* The sick man was at once given quinine in solution by mouth and by injection. He made a good recovery. Ferriman writes: "The activation of latent malaria by a non-malarial illness was uncommon in the area." It is very common in other parts of the world; influenza is one of the most troublesome resurrectionists. Most people will agree upon the value of his remark: "Definite tenderness under the left costal margin in the absence of a palpable spleen." Samuel Pepys wrote, on Nov. 5, 1665: "All our physicians cannot tell what an ague is, and all our arithmetique is unable to number the days of man."—I am, etc.,

Frank Marsh,
Pathologist, Anglo-Iranian Oil Company.

Shall we Nationalize Medicine?

Sir,—Prof. Ryle's letter (March 31, p. 456) scarcely calls for more than my assurance that he is right in thinking that a difference of opinion on the merits or demerits of nationalizing medicine cannot disturb the mutual respect and esteem of many years' standing.

And yet I must dissent from the suggestion that the doctor not being "political" implies the assumption that he cannot be both a good doctor and a good citizen. I have stated elsewhere that I believe the doctor to be potentially the most useful citizen the community possesses because the contribution he is able to make, through medicine, is of such vital importance to his fellows.

Confusion results from the use of the word "politics" in two senses—the sense of civil administration, and the sense of party or partisan influence. When medicine infiltrates politics it is at the former, and higher, level that it operates; when politics infiltrate medicine it is, unfortunately, at the latter, and lower, level. Prof. Ryle's acknowledged mental integrity is proof against any suspicion that he, personally, would help to sabotage the tremendous social service which the profession of medicine, of which he is so distinguished a member, is able to confer upon the nation. But some of us are a little anxious lest he be taken off his feet by the ground-swell of what, while claiming to effect an advance in the people's interest, would really be a stifling totalitarian agitation.

Prof. Ryle thinks we can only settle the issue by the method of trial and error, whereas I suggest that we think again before making such a perilous venture.—I am, etc.,

London. Horder.

Examinations in Stages

Sir,—The last paragraph of Capt. H. B. Hewitt's letter (March 17, p. 387) raises an important issue applicable to other examinations—namely, whether it is essential to pass an examination in all parts at one sitting or not.

The Conjoint Board, which is an essentially practical body, permits the passing of its examinations in stages from "pre-medical" to "finals." For example, anatomy or physiology may be passed separately if at least a few marks are obtained in the unsuccessful subject. At the next sitting it is only necessary to take one subject. Until last year in the Second M.B. it was necessary to pass anatomy, physiology, and pharmacology at the same time. The regulation has now been modified so that pharmacology may be taken separately.

For the Primary F.R.C.S. it is insisted that anatomy and physiology be passed at the same time, so there are many candidates who have passed in both subjects on different occasions. This illustrates one of the failings of examinations in their present form, for surely the fact that a subject has been passed should indicate that the candidate has sufficient knowledge with which to satisfy the examiner. As the Primary F.R.C.S. is not a qualifying examination it is impossible under present conditions to take time from clinical medicine to work full time. This being so it might surely be considered whether the parts could be passed separately. This need not entail lowering the standard—an expedient to be strenuously avoided, especially during war when so many standards inevitably deteriorate.—I am, etc.,

London, W.1. P. F. Kennish.

Obituary

Sir THOMAS LEWIS

Dr. Ivor J. Davies (Cardiff) writes:

Thomas Lewis spent his preclinical years at University College, Cardiff, where his exceptional ability was soon recognized. He took the science degree of the University of Wales in his stride with first-class honours in both anatomy and physiology. A natural aptitude for research became evident in his physiological studies and was promptly encouraged by his teachers—the late Prof. J. Berry Haycraft and his demonstrator Swale Vincent, from whom Lewis soon acquired a perfection of method in experimental technique. Swale Vincent afterwards did valuable research work with Schäfer at Edinburgh and later was professor of physiology at Winnipeg and finally at the Middlesex Hospital. The association with Swale Vincent must have had a most inspiring influence on Lewis's early urge to research work. He used the stethoscope and went occasionally to the Infirmary to listen to hearts, normal and otherwise, and it was perhaps here that he first became aware of the frequency of the functional systolic murmur. He was expert with the sphygmograph, and his pulse tracings were the envy of his fellow students. Lewis was reserved by nature, but became friendly with those who could join him in country pursuits around his old home, and his life-long hobby was a keen interest in birds. The British Association held its annual meeting at Cardiff in 1920, and it was eminently fitting that Lewis was president of the Section of Physiology on that occasion. The completion of our school of medicine was impending and Lewis was prepared to stimulate public interest at one of the Association meetings, but the College authorities of that day disapproved. Lewis was naturally indignant always with anything which obstructed progress. The school of medicine was completed in the following year as a separate college of the University. The air raids compelled the evacuation of the medical school of University College Hospital, and Cardiff was proud to accept a large number of its students with some of their full-time teachers. We were further honoured when Sir Thomas Lewis came for twelve months to share in the teaching of the London students, and we all profited immensely. He told me how refreshing it was to teach general medicine again, and reaffirmed his conviction that a sound experience of general medicine was an absolute necessity before specializing in any section of it. He was elected to the honorary staff of our hospitals and was himself stationed at the Llandough Hospital, but would readily come to see any case of particular interest at the Royal Infirmary, where he had obtained his earliest clinical knowledge of the circulation. Wales will always honour him as one of her most illustrious sons who achieved great academic distinction in her University and whose wonderful skill was afterwards applied to beneficent and epoch-making discovery in medicine.

We learn with regret of the death of Dr. **Samuel Burns Carlisle**, of Dromore, Co. Down, which took place in the District Hospital, Banbridge, on Feb. 24. Born in 1899, he was educated at the Royal Belfast Academical Institution and the Medical School of the Royal College of Surgeons in Ireland, where he obtained the L.R.C.P.I. and L.R.C.S.I. in 1923. After acting as house-surgeon and house-physician in the Meath Hospital, Dublin, and as an assistant medical superintendent in Peamount Sanatorium he took up his late father's practice in Dromore. He joined the B.M.A. soon after qualifying, and was chairman of the Portadown Division in 1933–4. R. M. writes: Simple, honest, and unassuming, Dr. Carlisle quickly became the counsellor and friend of many. Though it would never have occurred to him to think so, he personified the noblest tradition of Ulster medicine. His complete selflessness, his innate sense of vocation, his quick sympathy and resource, and his diagnostic skill, which seemed to be at once instinctive and cultivated, all combined to make him the ideal family doctor. Indeed his high standard of service to others and his inability to refuse his aid at any hour probably were the predisposing cause of the duodenal ulceration which cut short his life.

We regret to announce the death on March 4 of Dr. W. H. **Lamplough**, who practised for many years at Alverstoke, Hants, with his elder brother Dr. Charles Lamplough. Wharram Henry Lamplough was born on July 18, 1878, and from Bedford Grammar School entered St. Bartholomew's Hospital and continued his medical education at Newcastle-upon-Tyne. He took the English Conjoint diplomas and the M.B., B.S. degrees of Durham University in 1903, and proceeded M.D. four years later, taking also the D.P.H. After house appointments at the Royal Hants County Hospital and the London Temperance Hospital he settled in general practice at Gosport and Alverstoke, becoming police surgeon for the district, joint medical officer to the post office, and M.O.H. and school medical officer for Gosport. He served in the last war for a year as temporary lieutenant, R.A.M.C., and in 1923 was appointed honorary medical officer to the Gosport War Memorial Hospital and medical superintendent of the Isolation Hospital at Elson. Dr. W. H. Lamplough was a member of the Hants County Panel Committee continuously from 1915, and at the Annual Meeting of the B.M.A. at Portsmouth in 1923 was hon. secretary of the Section of Public Health. A man of fine physique, he was a good lawn tennis and badminton player and won the Hants golf championship in 1912.

Dr. **Alexander Smith Allan**, late of Calcutta, died on Feb. 4 at Montacute Gardens, Tunbridge Wells, in his 76th year. He studied for the medical profession at Glasgow University, graduating M.B., Ch.B. in 1897, and after a course in tropical diseases at Liverpool took the D.T.M. ten years later. He had been an officer of the Indian Auxiliary Forces Medical Corps, retiring with the rank of major, and received the Volunteer Decoration; he was also an Esquire of the Order of St. John of Jerusalem. Dr. Allan joined the British Medical Association in 1901.

Dr. **George Francis Whyte**, for many years a well-known practitioner in Dundee, collapsed and died on March 6 while on duty as chairman of the Dundee Medical Board. He was born in Nairnshire on Jan. 5, 1873, son of the Rev. John Whyte, and was educated at Nairn Academy, at George Watson's College, Edinburgh, and at Edinburgh University. He graduated M.B., C.M.Ed. in 1896, and went to Dundee at the turn of the century. He was assistant surgeon to the Dundee Royal Infirmary 1907–12, served throughout the last war as an officer of the R.A.M.C. Territorial Reserve, reaching the rank of lieut.-colonel, and was awarded the Croix de Guerre with gold star and the Territorial Decoration. Dr. Whyte, who joined the B.M.A. 45 years ago, had held office as president of the Dundee Branch, was a past president of the Forfarshire Medical Association and vice-chairman of the St. Andrew's Ambulance Association; he had also been chairman of the Dundee Panel Committee. He retired from practice in 1938, but came back into harness as chairman of the Medical Recruiting Boards for the Dundee area. He is missed by his colleagues and by many friends.

Dr. **Alexander Reid** of Bolton died on March 14 aged 67. He was born at Radcliffe of Scottish descent and served an apprenticeship to teaching at a school there, and then studied at Owens College, Manchester, taking his B.Sc. in 1900, and afterwards working for a time as a science master. He returned to Manchester to study medicine and graduated M.B., Ch.B. in 1911. He served during the last war with the R.A.M.C. in France and Belgium, and in 1918 started general practice in Deane Road, Bolton. Dr. Reid joined the B.M.A. in 1918, was vice-chairman of the Bolton Division in 1940–4, and represented it on the Lancashire and Cheshire Branch Council for eight or nine years. During the winter of 1940–1 he and Mrs. Reid made nightly visits to all the air-raid shelters in the district, and he had not taken a holiday since the war began.

A memorial service for Sir Thomas Lewis, arranged by University College Hospital, was held on March 27 at St. Pancras Church. There was a large attendance of colleagues and friends, and of students and members of the nursing staff from U.C.H. Sir Henry Dale, P.R.S., gave a commemorative address from the pulpit.

The Services

Lieut.-Col. (Temp.) H. W. Featherstone, R.A.M.C., has been appointed O.B.E. (Military Division), and Capt. O. S. Hetherington, New Zealand Military Forces, has been appointed M.B.E. (Military Division) in recognition of gallant and distinguished services in the field.

Capt. (Temp. Major) T. Affleck, R.A.M.C., has been appointed M.B.E. (Military Division) in recognition of gallant conduct in carrying out hazardous work in a very brave manner.

Capt. S. S. Nazir, I.A.M.C., has been awarded the M.C. in recognition of gallant and distinguished services in Burma.

The following awards and mentions have been announced in recognition of gallant and distinguished services in North-West Europe:

M.C.—Major (Temp.) E. G. Wilbraham, and Capts. J. O. Forfar and A. G. S. Hill, R.A.M.C.

Mentioned in Dispatches.—Major-Gen. Sir Percy S. Tomlinson, K.B.E., C.B., D.S.O., K.H.P., and Brig. (Temp.) E. Phillips, C.B.E., D.S.O., M.C., late R.A.M.C. Cols. (Temp.) D. L. Kerr, T.D., W. H. Marston, T.D., P. E. D. Pank, J. H. C. Walker, and R. F. Walker, C.B.E., M.C.; Lieut.-Cols. (Temp.) C. W. Arnot, O.B.E., M.C., C. Bainbridge, C. E. Gallagher, A. F. Kennedy, N. J. Logie, T. F. Main, J. J. Myles, W. P. Purvis, J. M. Scott, J. L. Warner, F. W. A. Warren, and G. N. Wood; Lieut.-Cols. (Acting) R. D. Jones, G. M. Robertshaw, and J. Smith; Majors C. R. Clayburn, M.B.E., C. H. Davies, and J. O'Kane; Majors (Temp.) W. G. Bateson, D. E. H. Beattie, R. A. Binning, J. Clay, H. A. Constable, D. O. Davies, A. S. Dill-Russell, W. N. Douglas, R. G. Evans, F. S. Fiddes, T. F. R. Griffin, F. M. Hanna, J. Hoile, D. F. Hutchinson, W. B. Hynam, R. N. Lees, M.C., J. B. MacKay, J. Millar, J. A. V. Nicoll, D. N. Parry, G. F. Petty, R. J. Phillips, R. Strang, J. M. Tait, A. F. Wallace, D. J. Watterson, J. W. S. Welborn, and K. S. Wilson; Capts. P. St. G. Anderson, H. W. C. Bailie, J. H. Balmer, E. S. Bompas, W. J. Cameron, A. J. Clarke, H. Conway, P. W. M. Davidson, R. Dobson, R. C. Droop, J. O. Forfar, J. G. Gant, C. N. Gibb, R. D. Glaister, F. I. Herbert, E. K. Hole, C. G. Irwin, L. P. Lassman, H. J. C. J. L'Etang, A. W. B. Macdonald, B. Maddison, M. Makin, T. S. Maw, L. H. H. May, D. G. McConnell, J. L. McNeill, C. W. Mearns, A. D. Milne, A. D. Payne, W. Rankin, R. L. Rees, S. McR. Reid, H. A. Ripman, N. C. Rogers, G. F. Shaw, G. M. C. Smith, A. U. Somerville, G. K. Spruell, R. T. Thin, I. F. Thomson, C. H. Watts, H. L. Waugh, and C. F. Young, M.C.; Lieuts. W. N. Coombes, R. A. Green, J. S. Hayward, J. A. Hogarth, and R. H. A Ledgard, R.A.M.C. Lieut.-Cols. C. U. Letourneau and T. M. Sieniewicz; Majors G. C. McGarry, J. C. McKellar, R. B. Murray, and H. A. Williams; Capts. K. A. C. Clarke, J. H. Fraser, and H. Marantz (killed in action); Lieuts. M. T. Cooper, R. Frechette, and J. Mackie, R.C.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Universities and Colleges

UNIVERSITY OF MANCHESTER

PROPOSED CHAIR OF CHILD HEALTH

At a recent meeting, reported in the *Manchester Guardian*, Lancashire maternity and child welfare authorities gave support to the proposal to establish a Chair of Paediatrics and Child Health at Manchester University. The delegates agreed to ask their local authorities for financial aid for the project and to report back to a further meeting in September. Dr. F. E. Tylecote, chairman of Manchester Public Health Committee, who presided, said that in 1942 the boards of management of St. Mary's Hospitals for Women and Children and of the Manchester Royal Infirmary addressed memoranda to the Manchester, Salford, and Stretford Joint Hospitals Advisory Board recommending such a department in the University. The Council of Manchester University were eager to support a professor of child health, but lacked the necessary funds. The setting up of such a department would obviously affect the whole of the area influenced by the University Medical School, and the Manchester Public Health Committee agreed to call this conference with a view to ascertaining what amount of financial support was likely to be forthcoming from the local authorities in that area. Dr. Tylecote contrasted the infant death rate in the industrial North, which in many towns is 60 or more per 1,000, with more-favoured climates, where the rate drops to about 30. The appointment of a professorship in paediatrics, he believed, would do much to improve that position. The purpose would be to remedy the very great shortage of consultants and specialists in child health and also the lack of refresher courses for medical practitioners. There was an undoubted need for more specialized training of medical students in these matters, and many doctors now in the Forces would come back after long absence wishing to brush up their knowledge of child health. The services and advice of the professor would be available to all hospitals and contributing authorities. Manchester University would be responsible for the capital charge if the local authorities would provide £10,000 a year, the maintenance cost, for a minimum period of ten years.

UNIVERSITY OF LEEDS

The Vice-Chancellor, presiding at a graduation ceremony on March 24, referred to the announcement by the Chancellor of the Exchequer of a grant of £1,000,000 a year for two years for the medical schools of the country. This sum, he said, should enable a good start to be made in the much-needed developments contemplated by all the schools in their post-war programmes. Active preparations were in progress in the University of Leeds for the expenditure on its own developments of whatever sum might be allocated to it. The two great needs were staff and buildings. Money alone could not meet them; but whatever was practicable would be done. The establishment of a whole-time Chair in Psychiatry, through a grant by the Nuffield Trustees, should give a lead to a notable advance in psychological medicine in that region of Yorkshire. It was hoped that with contributions from other sources the University would soon possess a complete psychiatric unit serving a wide area. A desirable change in the medical course had been the resumption of the three-year clinical period.

The following candidates have been approved at the examinations indicated:

M.D.—[1] O. Magidson, J. Overton, Lydia A. Wilson.

FINAL M.B., CH.B.—*Part II:* G. R. Fryers, Rhoda M. Allison, E. G. Brewin, Alice E. Buck, K. J. Burnett, P. S. R. Burrell, O. P. Edmonds, R. T. D. Franklin, W. I. M. Gibson, Gertrude Harris, G. W. J. Hawbrook, Edith V. Heritage, Dorothy D. Jones, O. G. Jones, Catherine M. Lamplugh, J. Lintin, D. H. McMillan, Marjorie S. Oxley, D. S. Smith, H. H. Smith, J. G. Smirk, Stella A. Speight, Monica C. Summerscales, E. J. S. Townsend, W. R. Walker, R. W. Wilkinson.

The following scholarships and prizes have been awarded:

Infirmary Scholarship: E. W. Green, J. H. Shoesmith; West Riding Panel Practitioners' Prize: R. J. Scothorne; Littlewood Prize in Anatomy: E. W. Green; Waddington Prize in Anatomy: Audrey W. Gillott.

[1] With distinction. [2] Second-class honours.

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examinations indicated:

FINAL M.B., CH.B.—*Part I:* F. G. Anderson, Olive M. Bell, A. J. Borkin, J. H. Brenner, Mary E. Casper, Beryl G. Castell, J. W. Bowie, [1,2] J. C. Davis, E. Dewsbury, W. M. Edwards, W. Ellenbogen, Jeanne A. Elphick, H. C. Endbinder, D. W. A. Evans, A. J. Farmer, Sheila K. Fraser, [2] T. H. H. Green, G. I. T. Griffiths, M. F. Holt, Elizabeth Howorth, A. B. Jones, E. Jones, S. Kalinsky, H. Keidan, F. D. Kitchin, F. P. Lennon, G. H. Lucas, Cicely D. Lyons, Edith G. Mercer, J. Moloney, [1,2] Janet H. Mountford, J. M. Old, W. L. Owen, Dorothy C. Peterson, [2] J. S. Porterfield, J. E. Riding, L. Robinson, D. L. Sharples, Audrey A. Shone, G. C. Slee, W. B. Smellie, R. J. Smith, Basha Taylor, Dorothy E. M. Thomas, W. A. L. Thompson, B. Towers, M. H. Turner, Pamela J. Tyson, D. G. Walker, Barbara M. Webber, H. H. Whincup, L. C. Wolfman, Jessie I. Young. *Pharmacology and General Therapeutics:* I. L. Francis, G. Frow, Alicia J. Middle. *Part II—Forensic Medicine and Toxicology:* Audrey M. Ashcroft, N. L. Bailey, K. Baker, S. Beacon, D. T. Binns, R. Brearley, P. M. Bretland, Cécile N. Broster, G. B. Brown, J. H. E. Carmichael, Helen A. Cawson, M. H. Clark, N. Coulshed, S. Croft, Pauline M. Dean, R. L. Goldson, H. C. Graham, E. A. Harris, Ailsa M. Heath, G. C. Hunter, F. G. Ince, R. W. Kennon, Barbara M. Killick, T. S. Law, Jean Learoyd, A. C. Levinson, H. S. Levy, T. R. Littler, J. A. O'Garra, A. E. Pritchard, Rachel M. Rawcliffe, G. P. Reed, H. Roberts, W. G. Roberts, P. W. Robertson, Olive R. Rodgers, K. S. Shaw, F. W. Sheffield, H. H. Slack, Helen M. Taylor, L. Temkin, Dorothy E. M. Thomas, R. G. Thomas, Maureen M. Tickle, L. F. Tinckler, W. R. Wallace-Jones, J. Ward, Joyce Watson, N. P. Watson, W. F. Wille, E. H. Wilson, [3] Esmé M. Wren, Aline N. Wynroe. *Public Health:* M. H. Clark, S. Croft, P. Hampson, R. W. Kennon, T. S. Law, Rachel M. Rawcliffe.

[1] Distinction in Pathology and Bacteriology. [2] Distinction in Pharmacology and General Therapeutics. [3] With distinction.

UNIVERSITY OF WALES

WELSH NATIONAL SCHOOL OF MEDICINE

The following candidates have satisfied the examiners at the examination indicated:

M.B., B.CH.—*Medicine:* J. W. Bowen, D. H. Davies, L. G. G. Davies, Joan Guy, J. C. Ham, D. I. Harries, B. E. Heard, R. M. E. Seal, D. R. Thomas, D. V. Thomas, Glenys M. Thomas, P. R. J. Williams. *Pathology and Bacteriology:* Gwenllian M. Griffith, N. E. H. Jones, D. M. Rowlands, Jean T. Smith, K. P. Williams.

UNIVERSITY OF ST. ANDREWS

Lieut.-Col. Stuart McDonald, M.D., R.A.M.C., has been appointed to the Chair of Pathology in the University.

UNIVERSITY OF DUBLIN

SCHOOL OF PHYSIC, TRINITY COLLEGE

The following medical degrees were conferred on March 14:

M.CH.—T. L. Lawson, E. E. O'Malley.

M.B., B.CH., B.A.O.—W. Burns, Isabel M. Crotty, Moira Danaher, R. M. Dooley, M. J. Doyle, L. Grant Duff, R. R. Hamilton, L. A. Kerwood, T. C. T. Killen, E. W. McBirney, J. D. McKeever, D. O'Connell, Katharine B. F. Orr.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At the statutory Comitia held at the College on Monday, March 26, Lord Moran was re-elected President for the ensuing year.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

The following lectures will be delivered at the College (Lincoln's Inn Fields, W.C.) at 4 p.m. on each day: Friday, April 6, Hunterian Lecture by Prof. H. S. Shucksmith, "Abdominal Injuries in Battle Casualties"; Thursday, April 12, Robert Jones Memorial Lecture by Prof. F. Wood Jones, "Some Reflections on his Teaching of Myology"; Monday, April 16, Thomas Vicary Lecture by Surg. Rear-Adml. G. Gordon-Taylor, "Medical and Surgical Aspects of the '45 (the Jacobite Rising of 1745)"; Wednesday, April 18, Hunterian Lectures by Prof. D. M. Stern, "Aetiology and Treatment of Prolapse, with Special Reference to Cystocele and Stress Incontinence"; Monday, April 23, Squad. Ldr. T. Cradock Henry, "Aviation Injuries of the Face"; Wednesday, April 25, Prof. Jean M. Dollar, "Use of Plastics in Ophthalmic Surgery"; Friday, April 27, Squad. Ldr. D. N. Matthews, "Storage of Skin for Autogenous Grafts"; Monday, April 30, Prof. A. K. Monro, "Treatment of Acute Appendicitis—with Special Reference to 1,000 Cases." The lectures are open to medical practitioners and advanced students.

Medical Notes in Parliament

Deafness in Ex-Service Men

In the House of Lords on March 14 the DUKE OF MONTROSE asked what progress had been made by the Medical Research Council toward the supply of standard national acoustic aids for deafened ex-Servicemen. He advocated approved otological clinics in all large cities. He said the late Lord Dawson had promised to support that proposal. The Medical Research Council had formed three committees to go into the question of deafness. One dealt with the medical and surgical side. Another dealt with education. A third committee dealt with aids and all kinds of assistance. Only one doctor was on it. The committee should be broadened. Lord HAMPTON asked whether the Government possessed through the medical services information on what degree of deafness they could expect to result from service in particular arms such as tanks.

Viscount CLIFDEN said the numbers of ex-Service men involved were relatively small. He doubted whether a network of clinics would be justified at present. Few otologists were available. Up to January, 1945, cases of ear diseases attributed to service in the armed Forces since the beginning of this war were: Navy, 500; Army 3,800; Air Force 700. The numbers recommended by aural surgeons for hearing aids had averaged fewer than 60 a year. Any recommendation made by the Medical Research Council for a more comprehensive scheme of rehabilitation applying to both civilians and ex-Service personnel would be sympathetically examined. The Ministry of Pensions had 16 regional offices where all deaf cases were seen by aural specialists.

Food Parcels for British P.O.W.s

On March 20 Lieut.-Cmdr. JOYNSON-HICKS asked the Secretary of State for War whether, in view of the special transport difficulties in supplying foodstuffs to our prisoners of war in Germany, dehydrated foods and vitamin tablets were included in the consignments under delivery, and what proportion of the consignment they represented. Sir JAMES GRIGG said that this suggestion would be borne in mind, but the efforts of the International Red Cross Committee and S.H.A.E.F. were at the moment concentrated on developing means of transport to get the prisoners supplies in the form they already knew and understood—namely, standard food and medical parcels from the National Red Cross Societies concerned. Large stocks of these were already in Switzerland. The first lorry convoy from Switzerland had reached its destination and distributed food parcels to some 18,000 British and United States prisoners in Bohemia. Further convoys were now on their way from Geneva.

The Whiter Loaf

Col. LLEWELLIN, replying on March 21 to Dr. Summerskill, said there was no consultation with the Scientific Advisory Committee, the Special Diets Committee of the Medical Research Council, or the Nutrition Committee of the Ministry of Health before the extraction rate of wheat was reduced below the 1942 standard. The committee consulted was the Standing Committee on Medical and Nutritional Problems. He added that the present whiter loaf was mainly composed of the new national flour of 80% extraction. According to the advice given to the Government before the extraction rate was altered, and according to the tests since taken, there was no appreciable loss in nutritional value compared with the previous loaf. The Government did not intend to reduce the extraction rate further unless and until it was satisfied that the reduction would not be detrimental from the nutritional point of view.

Payment for Services of Doctor's Wife

Dr. SUMMERSKILL inquired on March 22 whether wives of men conducting a business or profession from their homes could receive payment for services rendered in answering telephones, taking messages, etc., which could be treated as the wife's earned income for the purposes of income tax; and what was the maximum payment permitted before tax became payable.

Sir JOHN ANDERSON replied that the general rule of the income-tax law was that no allowance was to be made for expenses which were not wholly and exclusively incurred for the purpose of the trade or profession. The application of this rule depended upon the facts of the particular case. The decision in any particular case rested ultimately with the appropriate appellate tribunal. Speaking for himself, he would not regard a wife as an employee merely because she answered her husband's telephone calls or took his messages.

Dr. SUMMERSKILL asked why the B.M.A. informed doctors in the *British Medical Journal* that they were entitled to remunerate their wives for services rendered in connexion with the practice up to £89 with exemption from income tax.

Sir JOHN said he took no responsibility for the actions of the British Medical Association.

Water Pollution Research

Mr. ATTLEE, in reply on March 22 to Mr. Price, reported that the Water Pollution Research Organization had been carrying out a programme of research into the improvement of water supplies, including methods of water softening, treatment of water to reduce solvent or corrosive properties, the effect of chlorination, and the quality of drinking-water. During the war this programme had been interrupted by the need for investigating urgent problems of importance to the war effort. The study of the treatment of sewage and other effluents was only a part, though an important one, of the organization's work. Detailed plans for the extension of the work of the organization after the war were being drawn up.

Free Choice of Doctor for Old Age Pensioners.—Mr. WILLINK, in reply to Mr. Price on March 8, said most persons in receipt of a supplementary old age pension were entitled to medical benefit under the National Health Insurance Acts with a free choice of doctor. Only a small proportion obtained medical treatment through the arrangements made by public assistance authorities. These arrangements could with his sanction include a choice of doctor. Sanction for arrangements of this kind had already been given to about thirty authorities.

Repatriation for Malaria.—Mr. SORENSEN on March 13 asked the Secretary of State for War after how many attacks of malaria soldiers fighting in Burma and Eastern theatres of war had to suffer before being considered for repatriation on medical grounds. Sir JAMES GRIGG: The general state of a soldier's health and not any fixed number of attacks of malaria determines whether he is repatriated to this country. If modern methods of treatment are properly applied, men need not normally be invalided to this country on account of malaria.

Unqualified Practice in Kenya.—Sir E. GRAHAM-LITTLE asked Col. Stanley on March 14 to investigate complaints that the Government, in the absence of direction by the General Medical Council, encouraged medical practice in Kenya by unlicensed persons in opposition to duly qualified and registered medical practitioners. Col. STANLEY said he had asked the Governor for a report on the subject.

Spinal Injections: Consent of Parents.—Sir JOCELYN LUCAS on March 15 asked Mr. Willink to give instructions that before a spinal injection or lumbar puncture was given to a minor the consent of the parents should first be obtained, except in cases of emergency. He said the practice varied in different hospitals. Mr. WILLINK replied that it was the general practice of hospitals to obtain the parents' consent in these circumstances. It would not be competent for him to give instructions to hospitals on the subject, but Sir Jocelyn's question would draw the attention of any hospital which had not made a practice of obtaining consent to the desirability of doing so.

Allowances for Tuberculous Persons.—On March 20 Mr. McNeil asked the Secretary of State for Scotland if he had considered the recommendation in the Medical Research Council report on mass miniature radiography of civilians that the scheme of allowances for patients suffering from acute pulmonary tuberculosis should be extended to all notified cases of tuberculosis. Mr. JOHNSTON said he was aware of what was stated in the report. The present special arrangements for payment of tuberculosis allowances under emergency powers at the cost of Exchequer funds were designed to encourage persons to give up work and to seek early treatment, and were not designed to meet the needs of the chronic sick or in non-pulmonary cases. The question of financial assistance to persons suffering from incapacity, including tuberculosis, was under consideration in connexion with the proposals on social insurance.

Colonial Medical Service Appointments.—On March 20 Dr. MORGAN asked the Secretary of State for the Colonies if he was aware that during the last six years medical applicants for British Colonial appointments had been interviewed by the appointments private secretary alone, and whether, as this official had no means of judging medical qualifications, this method of selection or recommendation would now be abandoned. Col. STANLEY said that at all formal interviews with applicants for appointments in the Colonial Medical Service it was the practice for one or more members of his medical advisory staff to be present. He did not see any reason for changing this procedure.

Penicillin Supplies in Colonies.—Asked on March 21 to state the extent to which penicillin is now obtainable in the various British Colonies, Col. STANLEY replied that supplies of penicillin were now available from the United Kingdom, the U.S.A., or Canada, as was most convenient, for civilian use on the same basis as in this country. This permitted treatment of all civilian cases for which penicillin was known to be effective.

The Panel List in London.—The numbers of doctors who on Jan. 1, 1945, had more than the specified numbers of London insured persons on their lists were: more than 3,000, 19; more than 2,500 (but not more than 3,000), 32; more than 2,000 (but not more than 2,500), 79—i.e., 130 out of a total of approximately 1,700 doctors. This information was given by Mr. Willink to Sir Robert Tasker on March 22.

Notes in Brief

During the financial years 1935–9 the total expenditure of the Medical Research Council was £970,364, and during the financial years 1940–4 it was £1,328,606.

The Royal Commission on Population, which is continuing to meet once a fortnight, has still a considerable volume of evidence to take and many aspects of the inquiry to investigate further. It is not possible to indicate the date when the Commission will report.

Mr. Herbert Morrison told Sir Wm. Beveridge on March 1 that he had under consideration whether in the next Bill on electoral matters there should be an amendment of the existing provisions relating to the machinery of university elections for the purpose of securing their conduct by secret ballot.

Mr. Bevin said on March 8 that he had no present intention of introducing legislation dealing with the employment of women in hospitals. In a recent speech he had suggested that employment of charwomen in hospitals in the manner they had been employed must be ended and must be put on a proper footing.

Mr. Willink has announced that he is not prepared to ensure that expectant and nursing mothers can secure supplies of "natural unpasteurized milk." He told Mr. W. J. Brown that it is not practicable at present to supply safe milk except by pasteurization and by handling it throughout with strict hygienic precautions.

Mr. Herbert Morrison announced on March 22 that he proposed to arrange a full public inquiry into the circumstances which led to the boarding out of Denis and Terence O'Neill at Bank Farm, Minsterley, and the steps taken to supervise their welfare.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* infectious diseases increased in prevalence, measles by 217 cases, scarlet fever by 197, diphtheria by 86, acute pneumonia by 63, whooping-cough by 25, and dysentery by 16.

Both scarlet fever and diphtheria showed the highest totals for three months. Scarlet fever was especially prevalent in the north-west and north midlands, where the cases rose from 467 to 558. Diphtheria notifications rose by 25 in Yorks North Riding, by 21 in Durham, by 14 in Lancashire, and by 10 in Northumberland. There was an increase of 39 in the notifications of whooping-cough in Yorks West Riding. The total for measles was the largest since registration began, the increase occurring mainly in the south; in the north the incidence actually fell. The largest increases over last week's totals were: London 426, Essex 308, Southampton 303, Sussex 115, Hertfordshire 109, and Glamorganshire 98; the greatest falls were: Yorks West Riding 375, Warwickshire 232, Gloucestershire 172, Staffordshire 112, Yorks North Riding 102, Middlesex 100, Worcestershire 99.

Dysentery notifications exceeded any weekly total, with one exception, for seven years. The chief returns were: London 45, Lancashire 39, Yorks West Riding 39, Dorsetshire 27, Kent 24, Suffolk 22, Surrey 15, Essex 15, Yorks North Riding 14, Devonshire 13, Lincolnshire 13, Derbyshire 13, Gloucestershire 11, Durham 11, Northumberland 10.

In *Scotland* dysentery notifications were 97 higher than last week, those for pneumonia 14 higher, and for whooping-cough 12 higher. Measles notifications fell by 67, those for scarlet fever by 26, and for diphtheria by 16. Dysentery was prevalent everywhere except in the north, the largest returns being Renfrew County 52, Edinburgh 49, Glasgow 23, Lanark County 21, Falkirk 15, Aberdeen County 15, Fife County 14, Stirling County 12, Aberdeen B. 10. One case of smallpox was notified in Glasgow.

In *Eire* diphtheria notifications rose by 10, but most of the other infectious diseases dropped in incidence. Diphtheria is still widespread, 22 cases being notified in Dublin C.B. and the remaining 75 cases covering 41 registration districts.

In *Northern Ireland* the notifications of diphtheria fell from 28 to 8, and measles notifications were 13 lower, but the returns for scarlet fever and whooping-cough were respectively 8 and 7 higher than last week.

Week Ending March 24

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,522, whooping-cough 1,453, diphtheria 499, measles 25,507, acute pneumonia 866, cerebrospinal fever 88, dysentery 420, paratyphoid 3, typhoid 8.

No. 11

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended March 17.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

---

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

A meeting of the Medical Society of the L.C.C. Service will be held at the Fountain Hospital, Tooting Grove, S.W., on Wednesday, April 11, at 2.45 p.m., when Dr. L. T. Hilliard will give a clinical demonstration on mental deficiency in children.

The Food Education Society (29, Gordon Square, W.C.1) has arranged the following lectures to be given at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C., all at 2.30 p.m. Monday, April 16, Mr. A. L. Bacharach, "Food—the Science, the Logic, and the Art"; Monday, April 23, Lord Portsmouth, "Food and Agriculture"; Thursday, May 3, Sir Adolphe Abrahams, "Food and Physique."

The *X*-ray Analysis Group of the Institute of Physics will hold its 1945 conference (the fourth in the series) on April 12 and 13 at the Royal Institution, London, under the chairmanship of Sir Lawrence Bragg. The programme includes a lecture by Prof. J. D. Bernal on "The Future of *X*-ray Analysis," and a series of papers on new and improved methods. Discussions are to be included on the equipment of a laboratory for *x*-ray analysis, the interpretation of *x*-ray diffraction by optical principles, and the proposal to convert *x*-ray wave-lengths to absolute values. Further particulars may be had from Dr. H. Lipson (honorary secretary of the Group), Crystallographic Laboratory, Free School Lane, Cambridge.

The annual meeting of the Medical Superintendents' Society will be held at B.M.A. House, Tavistock Square, W.C., on Saturday, April 21, at 2.30 p.m. and will be preceded by a meeting of the Council at 2 p.m.

On March 21 the Queen opened, at Nayland Hall, near Colchester, the British Legion's sanatorium and settlement for the treatment of Service women suffering from tuberculosis. The Queen was received by Sir Frederick Maurice, president of the British Legion, and was shown round the sanatorium by Dr. F. R. G. Heaf, honorary consulting medical director. At present there are about 200 patients there.

A ceremony in honour of William Harvey was held in the Department of Physiology of the Mexico Faculty of Medicine on Oct. 30, 1944, under the presidency of Dr. Alfonso Caso, rector of the university. The ceremony included the presentation of a bronze bust of Harvey, an address by the British Ambassador, and a paper on "Harvey's Place in the History of Scientific Methods in Biology," by Dr. J. J. Izquierdo, head of the department of biology.

Prof. James Mackintosh, Dean of the London School of Hygiene and Tropical Medicine, is visiting Sweden to lecture for the British Council on "Housing and Medicine," "Nutrition and Medicine," and other aspects of social medicine and health education in Britain. He will probably also visit Finland. Prof. Mackintosh hopes to obtain in Sweden information for inclusion in a report on housing which he is preparing for the British Government.

Among the first advance party of U.N.R.R.A. personnel who recently arrived in Yugoslavia is Dr. Kenneth Sinclair-Loutit, who was medical officer for Civil Defence in the Finsbury district, where he was in charge of the casualty clearing station. The U.N.R.R.A. group forms part of the Mission which the Anglo-American Military Liaison Organization has sent to Yugoslavia to assist the local relief authorities. Military relief supplies have already arrived on the Dalmatian coast and distribution has begun both in Dalmatia itself and in the Islands. As further supplies arrive, and rail and road communications with the interior are repaired, this area will be increased and further personnel will be called forward. The workers are at the moment engaged as agents of the military in distributing supplies, but an agreement is now being negotiated with the Yugoslav Government, under which U.N.R.R.A. will take over responsibility from the military authorities at the end of what is known as the "military phase."

The November, 1944, issue of *Surgery* contains a symposium on surgical lesions of the thyroid.

Sir Philip Manson-Bahr has been appointed honorary consultant physician in tropical diseases to the Ministry of Pensions.

The second Pan-American Congress of Ophthalmology, which was going to be held in Montevideo, has been postponed to the autumn of 1945.

Dr. A. G. Curphey, M.B.E., M.C., has been appointed an Unofficial Member of the Legislative Council of the Island of Jamaica, and Dr. L. A. P. Slinger, O.B.E., has been appointed a member of the Executive Council of the Island of St. Lucia.

Recent news of conditions in Holland and France is given by eye-witnesses in the March number of *The World's Children*, published by the Save the Children Fund, 20, Gordon Square, London, W.C.1, price 6d.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Post-immunization Diphtheria

Q.—*A boy was immunized by A.P.T. when about 2 years old. When 5 he had a severe attack of diphtheria, followed by post-diphtheritic paralysis and "heart trouble." The boy is now 7, and the mother would like to ensure there will be no more diphtheria. He is in good condition but has cardiac irregularity. What further procedure would you suggest? What value would a negative Schick test have in such a case?*

A.—After the boy's past contacts with the diphtheria bacillus and its products in the early immunization, the attack of diphtheria, and the treatment with antitoxin, his cell reactivity is probably somewhat altered. The Schick test may be of the pseudo-variety and may prove difficult to read. However, it is important to test and to read about the fifth or seventh day. If he is certainly Schick-negative you would be justified in telling the mother that his immunity is reasonably high, but since she wishes him to have very high protection you would recommend a further short course of two injections, the first being 0.1 c.cm. of A.P.T. (personally I should give this injection at the same visit as for the Schick test). If the Schick test were positive or doubtful I should be strongly inclined to give a second injection of A.P.T. about four weeks later. If my first dose of 0.1 c.cm. of A.P.T. produced a slightly sore arm—which would not be surprising in view of the boy's past experience—I should make the second dose of 0.1 c.cm.; otherwise use 0.5 c.cm.

Semen and Vasoligature

Q.—*What happens to the seminal fluid of a man upon whom the operation of bilateral vasoligature has been performed? Does it not exert back pressure on the seminiferous tubules with deleterious result?*

A.—The external secretion of the testis ceases after vasoligature, but, strange to say, atrophy of the tubules from back pressure does not usually occur. When the operation of vaso-epididymostomy is successful in short-circuiting a blockage in the epididymal canal spermatozoa reappear in the semen even although the blockage has existed for several years. It is quite true that spermatogenesis may cease in an obstructed testis, but as the seminiferous tubules do not degenerate it may later be restored.

Skin Lesions and Menstruation

Q.—*A student nurse aged 23 has had two attacks (1943 and 1945) in which the ears tingle; the hands suddenly feel hot, and then tingle. A blotchy red rash and profuse perspiration follow. About an hour later the feet are similarly affected. In the first attack she had a severe headache. Both attacks coincided with menstruation. She does not feel ill. Between the attacks the hands are rather cold but not moist. Suggestions as to diagnosis and treatment will be welcomed.*

A.—An association between skin lesions and menstruation is well established. All manner of lesions are described, and although allergy plays a part in some the explanation of most is conjectural. Usually, however, a vascular change is fundamental, and this is similar to the one which takes place in the endometrium. An initial vascular spasm followed by dilatation and increased fragility and permeability of capillaries has been demonstrated in the skin during menstruation (not confirmed by all workers). The autonomic nervous system may also be involved, and it may be that oestrogens can bring about a liberation of acetylcholine not only in the uterus but also in the skin. There are, however, wide variations in the susceptibility of different tissues, and of different individuals, to reactions of this kind; an over-anxious or neurotic disposition appears to be an important factor determining the appearance of skin rashes, flushes, sweating, etc. In this case the infrequency of the attacks may be dependent on some emotional or other nervous upset at the time.

Treatment of such conditions is unsatisfactory and is both empirical and symptomatic. Clinical optimism and therapeutic vagueness are reflected in the varied remedies that have been tried—namely, oestrogens, progesterone, gonadotrophin, testosterone, calcium, vitamins C and K, snake venom, and ephedrine. As attacks are so infrequent it is doubtful whether any medicinal treatment is indicated. If there is a "nervous" element to the case, then clearly this should be treated. Otherwise simple treatment by limiting the intake of salt and fluid, and administering ammonium chloride 10 grains t.d.s. for seven days premenstrually—the usual measures to combat "menstrual tension states"—might be tried.

Gonorrhoea and the G.C.F.T.

Q.—*A female contracted gonorrhoea about 15 months ago; the complement fixation (G.C.F.T.) is positive. She refuses to go to the local V.D. clinic. What is the present treatment? Is it with sulphapyridine or sulphathiazole? Can she be considered cured when her complement fixation is negative? or would a urethral swab have to be taken before one could assume this?*

A.—A positive complement-fixation test for gonorrhoea (G.C.F.T.) present 15 months after the date of the original infection is generally considered highly suggestive, but not a proof, of persistent infection. Before instituting treatment it is essential, therefore, to know whether gonococci are still present, and if so where. For this purpose a careful clinical examination should be carried out and specimens for microscopical and bacteriological (cultural) examination taken from the urethra and cervix uteri; since a positive G.C.F.T. is often due to a closed focus of infection, particular attention should be paid to the glands of the cervix uteri, Bartholin's glands, and the Fallopian tubes. If gonococci are found treatment may be started; if they are not found, further examinations should be carried out immediately after the next menstrual period and repeated until the presence of gonococci can be confirmed or excluded; for the latter at least three monthly negative examinations are necessary.

As regards treatment, sulphathiazole is preferable to sulphapyridine: the optimum dosage is 5 grammes a day for 5 days, given in equally spaced doses (25 g.). If the patient was treated previously with sulphonamides she should be questioned as to signs of intolerance. During sulphonamide therapy the urine should be rendered alkaline with bicarbonate of potassium or sodium, and the fluid intake should be at least six pints per day. If one course of sulphathiazole fails to effect cure a second course of the same drug, or preferably of sulphadiazine, may be tried in the same dosage after an interval of 7 days, but a white cell count should be done first to guard against agranulocytosis. The sulphonamides often fail to effect cure in the presence of a closed focus of infection; in such cases other methods of treatment have to be adopted. A negative G.C.F.T. would be strong presumptive evidence of cure in this case, but should be supplemented by clinical and bacteriological examinations, as mentioned above. It should be borne in mind that the rectum is not uncommonly infected in the case of a female suffering from gonorrhoea.

Operation for Varicocele

Q.—*What are the late results of operation for varicocele as regards (1) recurrence; and (2) late atrophy of the testis?*

A.—Most surgeons do not recommend operation for varicocele save in very special circumstances, for the disability is usually so slight that it does not warrant the discomfort of the operation. Nor are the results such as to encourage one to operate. If the veins are excised recurrence is indeed very rare—under 2% according to Douglas. The chief drawback, however, is the damage done to the testis. J. Spotoft has recorded the late results of 27 operations, and his observations on this point deserve to be quoted: "The most remarkable changes are observed in the testicle, which in one-third of the cases only has kept its normal size and consistence. In one-third of the cases the testicular atrophy is so pronounced that the gland has been reduced to half or less than half its normal size." (*Acta chir. scand.*, 1942, **86**, 1.) This quotation is a sufficient answer to the second part of the question. It is true that larger series of cases have been reported on with a smaller percentage of testicular atrophies, but Spotoft's series were very carefully followed up and are likely to be accurate.

Age of Conception and Malformations

Q.—*What relation, if any, is there between the strength and mental ability of the offspring and the age of the parents at the time of procreation?*

A.—Any effect of paternal age at the time of conception of the child is at best so small that for all practical purposes the answer is "none." There are, however, a number of indications that the prenatal environment of the developing embryo becomes less favourable as maternal age advances. This manifests itself not so much in any small average effect on physical strength or intelligence as in an increased susceptibility to major accidents of development, provided that the underlying genetic basis is present. Much the most striking effect of increasing maternal age is seen in mongolism; the chance of bearing a mongol child rather more than doubles with each five years' advance in maternal age. A similar though much less pronounced effect is seen in connexion with certain other deformities—for example, anencephaly and congenital heart disease. It would seem that the normal human foetus is robustly protected against unfavourable prenatal influences. Certain genes, however, lower the margin of safety, so that some of their bearers react unfavourably at some critical stage of development. It is in all probability in some of these instances of lowered threshold to noxious influences that advanced maternal age reveals itself as an unfavourable factor. It should be emphasized, however, that although certain rather remote risks are considerably increased the absolute risk remains small. In the absence of definite indications to the contrary, no woman should be deterred from parenthood on account of age alone.

"Encephalopathic Attacks"

Q.—*What is the factor present in blood causing "encephalopathic attacks" in hypertension and chronic Bright's disease? Is there any treatment which will prevent them from occurring?*

A.—There is no known factor in the blood which causes "encephalopathic attacks," and there are no known concomitant changes in the blood chemistry. The attacks bear no relation to renal failure, and the only known association is with a raised blood pressure. This association is so common that the condition is usually called "hypertensive encephalopathy." An excellent review of the syndrome is given by A. M. Fishberg (*Hypertension and Nephritis*, 1939, Lea and Febiger). Prodromal symptoms usually give notice of an impending attack, which is in most instances preceded by a further rise in the already increased arterial pressure. The immediate cause of the attack is probably cerebral ischaemia, which is due either to local cerebral vasoconstriction or to oedema of the brain.

As the prodromal symptoms often give warning of an impending attack, preventive treatment is of considerable value. Venesection is frequently effective in stopping the attacks from developing and in ameliorating them if they have already occurred; the amount of blood removed is usually about 500 c.cm. Magnesium sulphate is also useful, 4–6 oz. of 50% solution being given by rectum. Sedation with chloral hydrate or morphine may be of value.

Anaesthetic Deaths

Q.—*What is the total anaesthetic mortality among the civilian population in Great Britain to-day (1) under 10 years, and (2) over 10 years of age? What proportion of these are people who are apparently healthy and in whom no cause for anaesthetic death is discovered? I am referring to death "on the table."*

A.—It is not possible from death certificates to distinguish deaths occurring "on the table" during anaesthesia from those occurring later as a result of, or whilst still under, the anaesthetic. All that these statistics can tell us is the number of deaths in the certification of which (usually by coroners) an anaesthetic was mentioned as a principal or contributory cause, classified according to the anaesthetic(s) used and according to the disease or injury on account of which it was administered. In a few instances it is stated that the anaesthetic was not a factor in the fatal issue, but whether this is stated or not all deaths with mention of anaesthesia are assigned by the Registrar-General to the disease or injury which necessitated the administration. In the rare instances in which no such reason for using an anaesthetic can be ascertained, the assignment is to the special group of "anaesthetic accidents." During the period 1941–3 the total deaths in England and Wales "under or associated with" anaesthesia according to death certificates averaged 144 annually at ages under 10 and 632 annually at ages 10 and over. Deaths assigned to the group "anaesthetic accidents" as defined above averaged 2 annually.

Sulphonamides during Lactation

Q.—*What dangers if any, either to the offspring or to the mother, occur when sulphonamides are given to a woman during lactation? What proportion taken by mouth passes into the maternal milk? Is any particular form of sulphonamide preferable?*

A.—When sulphonamides are given to a woman during lactation there are no special dangers owing to lactation, but only those which would be present with any adult person—e.g., cyanosis, rashes, renal lesions, etc. There is no danger to the offspring. The amount of sulphonamide which passes into the milk is approximately equal to the concentration in the blood—e.g., 3–13 mg. per 100 c.cm., according to the dosage. In extreme cases the child might receive up to 30–40 mg. sulphonamide per day, but usually it would be much less than this. These quantities are too small to be significant. The best sulphonamides to use are sulphathiazole or sulphadiazine, or, failing these sulphanilamide. Sulphapyridine should be avoided in case it causes nausea and interferes with lactation. For further information see Aguirre *et al.*, *Sem. méd.*, Buenos Aires, 1942, **49**, 621 (*J. Amer. med. Ass.*, **119**, 982); Foellmer, *Klin. Wschr.*, 1941, **20**, 913; Hepburn, Paxson, and Rogers, *Arch. Pediat.*, 1942, **59**, 413; Rieben and Druey, *Schweiz. med. Wschr.*, 1942, **72**, 1376.

Morphine and Cerebral Haemorrhage

Q.—*As morphine is often recommended for the treatment of shock and internal haemorrhage, would you advise an injection during the acute stage of a cerebral haemorrhage?*

A.—Morphine is given to patients with shock or internal haemorrhage for the relief of restlessness and pain. In cerebral haemorrhage these symptoms are absent, and it would be contraindicated on account of its depressant effect on the respiratory centre.

INCOME TAX

Sch. D or Sch. E: Cancellation of 1943-4 Tax

X. M.'s wife has for the past 8 years worked as a locumtenent for a local authority. Payment has been on a sessional basis for work done. She has been assessed under Schedule E, but the inspector of taxes contends that for 1943-4 (and presumably the earlier years also) the correct basis of assessment was under Schedule D, and therefore that she is not entitled to cancellation of the 7/12ths tax for 1943-4.

** Seeing that, apart from the £5 5s. casual consultation fees, Mrs. M.'s whole work has been for a single authority, and presumably done under the instructions of that body, there seems to be good ground for contending that this is a case of part-time employment and that the earnings were and are correctly chargeable under Schedule E. We suggest that that line should be taken and the inspector of taxes asked to reconsider his views. If the past year's liability were recalculated on a "Schedule D" basis the difference in tax would probably not be substantial; it would arise mainly from the allowance on books and subscriptions, as travelling expenses incurred between residence and place of work are not normally allowable under either schedule—as suburban workers in the city find to their cost.

LETTERS, NOTES, ETC.

Urea for Migraine

Dr. J. A. Brown (Birmingham) writes: In reply to a question on the use of urea in migraine (*Journal*, March 24, p. 431) a dose of 15 *grammes* t.d.s. is suggested. I have treated a considerable number of cases of migraine with success and have found the following dosage effective: 20 *grains* t.d.s. for one week; 20 grains twice daily for two weeks; 20 grains once a day for several months. Failure to continue the daily dose is frequently followed by a renewal of attacks of migraine. It is interesting to note that the suggestion made by Sir Walter Langdon-Brown that urea might be of some value in the treatment of obesity (probably due to water retention) in young women has been found to be effective. A dose of 60 grains t.d.s. has in some cases resulted in a reduction of 6 to 8 oz. per week for a few weeks.

Menstruation and Epilepsy

Dr. F. Newman (Marden, Kent) writes: As a patient of mine suffering from epilepsy at the menstrual period has had an artificial induction of the menopause by radium and has benefited very greatly as a result, I feel this information might be of help to the questioner whose problem is printed in the *Journal* of March 17 (p. 396). The patient was told by the surgeon that she might derive benefit and she might not. Under these conditions she agreed to risk it and is very thankful she did so.

Dr. J. Rabinowitch (radiologist, E.M.S.) writes: With reference to the problem raised in your issue of March 17 (p. 396) whether an artificial menopause would cure epileptic fits which occur only during menstruation, I would like to quote the following two cases: (1) A woman aged 50 had epileptic fits of considerable severity since her menarche at 15, at the rate of 4 to 5 attacks a week. Her menopause occurred when she was 43, and with her last period all fits ceased abruptly and she has never suffered from them since. (2) A woman of 33 who has oligomenorrhoea and spells of amenorrhoea lasting from 5 to 14 months has a few epileptiform seizures every 28 to 30 days. These are accompanied by loss of consciousness for a short while and a dazedness lasting about 48 hours, and are independent of whether there is any actual menstrual loss or not. My first case opposes the current view that the menopause has no influence on the occurrence and frequency of fits. The second case is similar to that of your correspondent, and shows that the fits are not actually caused by pain or the passage of clots but are probably due to a hormonal mechanism. Harris (*Endocrinology*, 1932, **16**, 29) records hypoglycaemic attacks associated with menstruation which frequently simulate epileptic convulsions. Whether these hypoglycaemic fits are caused by a hormonal imbalance leading to an oversecretion of insulin is not clear, but the coincidence of menstruation and convulsions would seem to incriminate either the ovaries or the pituitary gland. I would therefore suggest that, if possible, a temporary amenorrhoea only be produced by *x* rays, and the effect it has on the fits be observed first. If the fits cease, then I would resort to the more drastic complete artificial menopause. If the fits continue in spite of cessation of the periods it may be worth while irradiating the pituitary.

A Case of Scorpion Bite

Dr. E. G. Cohen writes from abroad: On Feb. 14, 1945, at 10 a.m. a sergeant reported that he had just been bitten by a scorpion while man-handling parts in an ill-lighted store. He complained of pain in the tip of the right index finger (where he had been bitten) with twinges of pain shooting up to the right axilla. The pain was not severe, and he felt perfectly well. On examination he was of good colour, with a pulse rate of 80 per minute, of good volume and tonus. No puncture wound was visible on the horny skin of the index finger, but slight oedema of his subcutaneous tissues was present. Pressure on the finger caused no further pain. The axilla was not tender, nor were any glands palpable. While a syringe and local anaesthetic were being prepared, a scalpel was flamed and the finger incised longitudinally for 3/8 in. on either side of the bite. Free bleeding resulted and the finger was agitated in warm hydrogen peroxide. Then the base of the finger was infiltrated with 3% local analgesic, in which was incorporated adrenaline, 8 c.cm. being used. Some two minutes after infiltration the man felt faint and rapidly turned yellow (owing to prophylactic mepacrine this is the colour of skin on blanching). He was seen to be copiously sweating and began to retch; the pulse was not palpable at the wrist. He was laid flat, covered with a blanket, and given hot tea and a hot-water bottle. When this had been done his heart rate was 100 and B.P. 85/60. After ten minutes he had recovered: B.P. 130/80, pulse 76. On questioning, he said the base of his finger soon went numb and this gradually spread down to the tip, which took about ten minutes before becoming free of pain. He was kept under observation for 24 hours, but there was no further oedema, pain, or circulatory collapse. Manson-Bahr has reported relief from pain immediately on application of liq. ammon. fort. or slowly with a more dilute solution. In his own case he incised the area and bathed with permanganate of potash, prior to infiltration with local analgesic and adrenaline. Circulatory reactions can be very severe in young children, and he advised the use of antiserum made by inoculation of horses with extracted scorpion venom. This can be used both prophylactically as well as therapeutically. The points of interest are (1) the relative inconsequence of a bite if the treatment (even if only symptomatic) is begun early; (2) the collapse a good two minutes after the infiltration. A psychological faint was considered unlikely, and pain though still present was not severe. Perhaps it was due to absorption of venom before adrenaline could slow this down by vasoconstriction.

Unusual Cause of Antenatal Death

Capt. G. Rhys Evans, R.A.M.C., writes: The following unusual cause of antenatal death might be of interest. During the fighting in Italy I was asked to visit a sick Italian woman at a rather remote farmhouse. On arrival I found a pregnant woman aged about 33, multiparous, with a small 2-days-old infected wound about McBurney's point. Her temperature was 102°, pulse rate 124, tongue furred and dry. She had twins; one head was engaged and movement could be felt. She refused to be evacuated, and I put her on sulphanilamide 2 g. 4-hourly for 24 hours and then 1 g. 4-hourly. Next day her condition was unchanged, but on the following day I found she had given birth during the night to one live twin boy and one dead. The latter had been killed by the piece of shrapnel which had penetrated his brain. Her temperature was now 100° and pulse 98, and I continued the sulphanilamide. Two days later when I had to leave the district her temperature and pulse were normal and both mother and child were doing well.

Antibiotic Action of Moulds

Capt. I. G. Anderson, R.A.M.C., writes: In the recent literature on penicillin I have seen no mention of a very early experiment to utilize the antibiotic action of moulds. Shortly before the war I came across a paper in the *Presse Médicale* about the year 1906-8 by A. Vaudremer, who described the clearing of a slope of tubercle bacillus culture by the mould *Aspergillus niger*. Further, the author suggested that this mould should be used clinically in tuberculosis. I believe he went further than that, as I also came across a reference to "Vaudremer's vaccine," but was unable to find any more details. Perhaps someone with better access to a library than I have would care to verify the above reference.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY APRIL 14 1945

RECENT WORK ON THE PHARMACOLOGY OF SULPHONAMIDES

BY

FRANK HAWKING, D.M.

National Institute for Medical Research, London

Under the heading of pharmacology it is convenient to consider all the actions of sulphonamide compounds on the body of the host, excluding the detailed discussion of the toxic symptoms encountered in clinical practice. On the whole, sulphonamides are rather inert from a pharmacological standpoint, and the greater part of any article on this aspect is necessarily occupied by a consideration of the factors involved in maintaining an optimal concentration at their site of action. The methods developed by Marshall and his colleagues for the estimation of sulphonamides in blood are too well known for consideration here. Bogen (1943) has described a simple method of testing urine to find if the patient has already received a sulphonamide. (A drop of urine is placed on wood-pulp paper—e.g., newspaper—and a drop of hydrochloric acid is added; with a sulphonamide a yellow colour appears.) Procaine (novocain) gives the same colour as sulphonamides in Marshall's test (which can thus be used for its estimation); consequently this and other local analgesics which contain the *p*-aminobenzoate group must not be used for the collection of specimens for sulphonamide estimations.

Absorption

When sulphonamides are taken by mouth they are rapidly absorbed. Apparently most of this absorption occurs in the upper part of the small intestine, but there is evidence suggesting that much may be absorbed through the stomach wall. Usually absorption is complete before the ileo-caecal valve is reached. Sulphanilamide and sulphathiazole are rapidly absorbed, sulphadiazine more slowly. The absorption of sulphapyridine is slower, less regular, and less complete than that of the other compounds (Kinsman, Moore, and Harrison, 1940). Absorption from the large intestine can occur, but the rate is slower (Turell, Marino, and Nerb, 1940; Marshall, Bratton, White, and Litchfield, 1940). In cases where oral administration is not possible—e.g., after operation on the stomach—sulphanilamide may be given per rectum, but the amount absorbed is always uncertain and the resulting blood levels tend to be low (Wood, 1941). Sulphapyridine and sulphadiazine are both poorly absorbed from the large intestine (Peterson, Strauss, Taylor, and Finland, 1941).

If the sulphonamide is given with an empty stomach it is absorbed slightly more quickly than if given after a meal; but the difference is not great enough to be of clinical importance or to compensate for the greater risk of nausea. Similarly the administration of acid or alkali at the same time as the sulphonamide does not appreciably alter the rate of absorption (Peterson and Finland, 1942; Wilson, 1943). When sulphapyridine, sulphathiazole, or sulphadiazine is given by tube direct into the duodenum, absorption may be greatly diminished, suggesting that a considerable portion of the sulphonamide may reach the blood stream through the stomach wall; this effect was not shown when sulphanilamide or sodium sulphadiazine was given (Peterson and Finland, 1942). Sodium sulphonamides have been suggested for oral administration in order to obtain rapid absorption, but their issue for this purpose has not received the approval of the Council on Pharmacy and Chemistry of the American Medical Association. It is claimed that the absorption of sulphanilamide can be accelerated by giving it as a solution with glucose, glycerin, and sodium lactate, or with sodium lactate and potassium citrate, but the difference is not great enough to be of clinical value (Siebert and Loose, 1940).

Sulphanilamide and the soluble preparations of the other sulphonamides are quickly absorbed when injected intramuscularly or subcutaneously. Absorption is of course most rapid (instantaneous) when the compound is injected intravenously. Absorption is also rapid from serous cavities, such as the peritoneum and pleura (Hawking and Hunt, 1942; Vickers, 1943), from large raw areas—e.g., burns—and from large wounds (depending on their size, shape, and vascularity); on the average, absorption from these sites is about half as rapid as from the alimentary canal.

Distribution

After absorption into the blood stream sulphanilamide diffuses through the whole body. In dogs, about 4 hours after an oral dose, the compound is distributed approximately evenly through all the tissues except bone and fat, and the concentration in the tissues is equal to that in the blood (Marshall, Emerson, and Cutting, 1937b). During the period preceding this phase of equilibrium the concentration in the blood is greater than that in the tissues; following this phase, the blood concentration is lower than the tissue concentration (Alexander, 1943). Although there is no tendency for the compound to be concentrated in any special tissue, some organs contain more than others. Thus during the first six hours (in rabbits), if the concentration in the blood is taken as 1.0, the average concentration in the liver is 1.2, in the kidney 2.0–3.6, in the brain about 0.6, and in muscle 0.8 (Alexander, 1943). According to some figures of Waterhouse and Shannon (1942) for dogs, if the concentration of sulphanilamide in the plasma is taken as 1.0, that in the erythrocytes is 1.4, in the lung 1.1, in the liver 1.3, in the pancreas 1.1, in muscle 1.1, in the cerebrospinal fluid and in the brain 0.6, and in nerves 0.76. In dogs no acetylation occurs and all the sulphanilamide is present in the free form. The distribution in the blood between the erythrocytes and the plasma differs somewhat with the different compounds. Thus if the concentration of the free form in the plasma is 1.0, that in the erythrocytes is:

Sulphanilamide ..	1.0–2.1	(Simesen, 1941a, 1941b; Reinhold, Flippin, Schwartz, and Domm, 1941; Ratish, Shackman, and Bullowa, 1942; Murphy, Clark, and Flippin, 1943)
Sulphapyridine ..	0.6–1.1	
Sulphathiazole ..	0.3–0.4	
Sulphadiazine ..	0.25–0.5	
Sulphamerazine ..	0.3	
Sulphacetamide ..	1.5	
Uleron	1.0	

Similarly as regards the penetration into the cerebrospinal fluid, if the concentration in the plasma is 1.0, that in the cerebrospinal fluid (when equilibrium is reached) is:

Sulphanilamide ...	0.7–1.0	(Marshall and Litchfield, 1939; Sadusk, Blake, and Seymour 1940; Banks, 1941; Long, 1941; Reinhold, Flippin, Schwartz, and Domm, 1941)
Sulphapyridine ..	0.7	
Sulphathiazole ..	0.15–0.4	
Sulphadiazine ..	0.5–0.8	
Sulphadimethylpyrimidine ..	0.4–0.8	(Macartney, Smith, Luxton, Ramsay, and Goldman, 1942)
Sulphamerazine ..	0.3–0.7	(Murphy, Clark, and Flippin, 1943)

(Probably the differences between the various compounds are due to the differing amounts "bound" to the plasma proteins; see below.) Actually the ratio (concentration in C.S.F./concentration in plasma) is lower than these figures during the earlier part of treatment, when the blood concentration is rising, and higher when administration of the drug is stopped and the blood concentration falls. Similarly, the concentration in peritoneal, pleural, and joint effusions tends to be somewhat lower than that in plasma when equilibrium is reached; but there is a lag of 2–3 hours in arriving at this position (Cantarow, Cubberley, and Rakoff, 1942). The concentration of sulphathiazole in the fluid of infected or uninfected knee-joints is approximately the same as that in the blood (Heyl, 1941). As regards the eyes, when sulphanilamide is given to dogs the concentration in the aqueous humour one hour later is about 33% of that in the blood, rising to a maximum of about 61% four hours after administration (Bellows and Chinn, 1939); when 100 mg. sulphapyridine was applied locally to the conjunctiva (of rats) the concentration one hour later was 47 mg. per 100 c.cm. in the conjunctiva, 30 mg. in the cornea, and only 5 mg. in the aqueous humour (P'an, 1941). The content of sulphapyridine in the pancreatic juice (of cats) after its administration by mouth is slightly less than that of the blood (Taylor and Ägren, 1940). [For bile, see under "Excretion."] Sulphanilamide is also found in menstrual blood; but in the normal secretion of the cervix uteri it is present in such small amounts that its bacteriostatic action is problematic.

The Foetus.—Sulphonamides pass through the placenta into the foetal circulation, and therefore there are possibilities of toxic and of therapeutic action. Speert (1943) recommends that in order to prevent bacterial invasion of the foetal blood vessels in cases of prolonged labour with ruptured membranes, and in cases where it is desired to protect the foetus against intrapartum infection by gonococci from the mother, the woman in labour should be given a single intravenous dose of 5 g. sodium sulphadiazine; during the next few hours concentrations of 9–11 mg. per 100 c.cm. will be maintained in the foetal blood and 10–20 mg. in the maternal blood. This procedure involves a possible (but low) risk of renal obstruction in the mother. Although prolonged treatment with sulphanilamide is injurious to the foetus (Adair, Hesseltine, and Hac, 1938; Speert, 1940), in animals or in human beings the danger from a single dose is probably small (Philipp, 1941).

Combination of Sulphonamides with Plasma Proteins.—Part of the sulphonamide in the plasma is bound in some way to the plasma proteins, and is not free to pass through a dialysis membrane. The combination with protein cannot be very strong, as sulphonamides are not precipitated to any large extent when the proteins of blood or serum are thrown down by trichloracetic acid in the first stage of Marshall's quantitative test. The combination apparently involves the plasma albumin principally, while the globulin and lipoids are not concerned (Davis, 1942). The higher the concentration of sulphonamide, the smaller the percentage of bound drug; the figures below refer to blood concentrations of the therapeutic range (2–20 mg. per 100 c.cm.). The amount bound is approximately proportional to the amount of albumin present. The binding is not diminished by denaturation of the protein with ultra-violet light (Davis, 1943). Similarly, red prontosil is combined with the albumin of the serum but not with the globulin, as was shown by Schönholzer (1940), using a cataphoresis technique. The extent to which this binding occurs differs with the different compounds, as shown below (Davis, 1942; Heinemann, 1943):

Sulphanilamide	12–20% bound
Sulphapyridine	40–45% "
Sulphathiazole	75–80% "
Sulphadiazine	55–60% "

Compounds similar to the sulphonamides but lacking the *p*-amino group, and acetyl derivatives of sulphonamides, are bound to the proteins in the same way (Davis and Wood, 1942). Apparently the bound drug is not bacteriostatic, although, as the combination is loose, it forms a store of potential activity. The occurrence of this combination with protein probably explains the different distribution of the various compounds between plasma and erythrocytes, and between blood and cerebrospinal fluid, which have been described above. In fact, the calculated distribution between blood and a dialysate through a membrane permeable to sulphonamides, but not to protein, agrees closely with that observed clinically between blood and cerebrospinal fluid. Such combinations with proteins may conceivably play a part in the production of such sensitization phenomena as drug fever and specific skin sensitivity.

Metabolism of Sulphonamides

As is well known, much of the sulphonamide compound introduced into the body is conjugated, especially with acetate, to form acetyl derivatives which are therapeutically inert, although equal in toxicity to the original sulphonamide. Sulphanilamide and sulphapyridine are more readily acetylated than sulphathiazole and sulphadiazine. On the average, about 20% of sulphanilamide in the blood and about 25–60% of that in the urine is in the conjugated state. With sulphapyridine, about 33% (10–45%) of the total compound in the blood and about half of that in the urine is acetylated in man (Kinsman, Moore, and Harrison, 1940). With sulphadiazine, the acetylated form accounts for about 10% of the compound in the blood and for about 25–33% of that in the urine (Peterson, Strauss, Taylor, and Finland, 1941). With sulphathiazole, about 20% of the compound in the blood is acetylated (Frisk, 1940a, 1940b), or 0–30% (average 12%) (Sadusk, Blake, and Seymour, 1940). The site of acetylation seems to be mostly in the liver (Harris and Klein, 1938), though in some animals other organs also can bring about this conjugation. Besides the sulphonamide inactivated by acetylation, there is evidence that part is combined with other compounds (especially glucuronic acid), or is degraded by other chemical processes. It has been shown by Simesen (1941a) that during the first day (in mice) up to 50% of the sulphanilamide may be destroyed in some way at present unknown, while 40–50% of sulphathiazole and of sulphacetamide is destroyed in this time; 40–50% of sulphapyridine is destroyed in 2–3 days, and 70% of uleron in 3–4 days. Alexander (1943) has confirmed this by giving sulphanilamide to mice and analysing the amount found in the excreta and in the (minced) body after various periods.

Excretion

i. *Urine.*—The main excretion of sulphonamides is through the kidney, the amounts passing out by other routes being comparatively insignificant. Part is excreted unchanged and part as the acetyl derivative, as has been described above. Apparently sulphanilamide passes out from the plasma into the glomerular filtrate and some of it is reabsorbed in the tubules. In dogs the sulphanilamide clearance is 20–30% of the creatinine clearance (only slight reabsorption in the tubules), so presumably 60–70% of the sulphanilamide in the glomerular filtrate is reabsorbed. The clearance is independent of the plasma level, but increases as the flow of urine is increased. In rabbits the clearance of the sulphanilamide is 30–40% that of creatinine and inulin, but the clearance of acetyl sulphanilamide is the same as that of these two compounds; presumably acetyl sulphanilamide is not reabsorbed in the tubules (Loomis, Hubbard, and Koepf, 1943). The average renal clearances in man for the original sulphonamides and their acetyl derivatives respectively are:

Sulphapyridine ..	23 and 58 c.cm. of plasma a minute
Sulphathiazole ..	43 " 55 " " " " "
Sulphadiazine ..	31 " 59 " " " " "

i.e., the amount of compound present in this volume of plasma is excreted by the kidney each minute.

As regards the proportion of the dose excreted in the urine various estimations have been given:

Sulphapyridine (usual clinical dosage): 60–90% (Frisk, 1940a), or about 30% (22–56%) (Kinsman, Moore, and Harrison, 1940). appears in the urine, about half being in the conjugated form.

Sulphathiazole: Daily excretion amounts to 75% of the intake (Simesen, 1941b), to 86–92% of the intake (Frisk, 1940b), or to 100% (Spink and Hansen), 1940).

Sulphadiazine: When 4–5 g. is given orally, 60% is excreted in urine in 24 hours, and 75% in 72 hours; a quarter to a third is in the conjugated form (Peterson, Strauss, *et al.*, 1941). Other data are given by Ratish, Shackman, and Bullowa (1942); Reinhold, Flippin, *et al.* (1941); and Sadusk, Blake, and Seymour (1940) When it is desired to increase the excretion of sulphadiazine (e.g., because of agranulocytosis) sodium bicarbonate should be given; to decrease the concentration in the urine (e.g., because of renal complications) large volumes of 5–10% glucose should be injected intravenously or much water may be given by mouth, intravenous injection of saline is less effective (Peterson, Goodwin, and Finland, 1943).

ii. *Faeces.*—The work of Marshall, Bratton, *et al.* (1940) on sulphaguanidine and the treatment of bacillary dysentery has directed attention to the amount of sulphonamide appearing in the faeces. Practically all such compound represents the portion which has not been absorbed during passage down the alimentary canal; very little represents true excretion by the bile or by the mucous membrane of the large intestine. Thus, when sulphaguanidine is injected subcutaneously into cats, only very small amounts appear in the faeces (Hawking, 1942b). When given as a short therapeutic course to man, sulphapyridine, sulphathiazole, sulphadiazine, and sulphanylbenzamide reach the faeces only in small concentrations—e.g., 0–70 mg. per 100 c.cm. (Hawking, 1942a). Uleron apparently reaches the faeces in about the same amount as sulphaguanidine; when 12–18 g. is given during 6 days, about 7 g. appears in the faeces and about 3–4 g. in the urine (Reimers, 1939; Marquardt, 1938). But no report on the use of uleron for bacillary dysentery has appeared.

iii. *Bile.*—Sulphanilamide and other sulphonamides appear in the bile only in concentrations about the same as those in the blood; no large amount of the acetyl derivative appears, so that, although it is formed in the liver, it is not excreted by this route (Hubbard and Anderson, 1940; Spink, Bergh, and Jermsta, 1941; Hubbard and Butsch, 1941). Accordingly sulphonamides are unlikely to have any special influence in cholecystitis beyond their general influence on inflammation anywhere in the body.

iv. *Other Secretions.*—Sulphonamides appear in most of the other excretions and secretions in concentrations similar to those of the blood. Sulphapyridine injected parenterally appears in the gastric juice (apparently by a process of physical diffusion: Davenport, 1942), and this may be the explanation of the vomiting which may occur in such patients. Sulphathiazole appears in the tears in concentrations of 0.1–1.0 mg. per 100 c.cm., but this is not the direct cause of the conjunctivitis which sometimes develops; such conjunctivitis is probably due to acquired sensitivity (Turkell and Wilhelm, 1941).

v. *Milk.*—Sulphonamides appear in the milk of lactating women in amounts similar to those of the plasma. Thus during a therapeutic course the milk may contain sulphanilamide up to 9 mg. per 100 c.cm. (Hepburn, Paxson, and Rogers, 1942), sulphapyridine 3–13 mg. per 100 c.cm. (Föllmer, 1941), or sulphathiazole 0.5–1.5 mg. per 100 c.cm. (Rieben and Druey, 1942), and the infant may receive sulphapyridine 30–40 mg. a day or sulphathiazole about 4 mg. a day. It is the general opinion that the amount appearing in the milk of the mother is too small to exert any effect, toxic or therapeutic, upon the infant.

Blood Concentration

The following Table shows typical blood concentrations after administration of the different sulphonamides:

Compound	Dose	Blood Concentration (mg. per 100 c.cm.)		Reference
		Free	Total	
Sulphanilamide	4 g.	4·0*		
Sulphapyridine	2–4 g. 2–4 g. followed by 1 g. 4-hourly	2·0 (0·5–5·0)* 4·2–6·5	2·6 5·6–8·6	Kinsman, Moore, and Harrison (1940)
Sulphathiazole	1 g. 4-hourly 2 „ „ 3 „ „	4·6 (1·6–8·7) 6·0 (2·2–13·2) 6·5 (3·0–9·6)		Melton (1941)
Sulphadiazine	2 g. 5 g.	2·0–3·3* 3·6–5·5*		Ratish, Shackman, and Bullowa (1942)
	4–5 g.	8·5 (6·7–10·8) (after 24 hrs. 2–4)	9·9 (7·9–12·6)	Peterson, Strauss, *et al.* (1941)
	3 g. followed by 1 g. 4-hourly	9·5 (4·4–19·0)	11·3	Reinhold, Flippin, *et al.* (1941)
Sulphamezathine	4 g. followed by 2 g. 6-hourly	6·0 (2·0–13)		Macartney *et al.* (1942)
Sulphamerazine	3 g. followed by 1 g. 6–8-hourly	10·3 (3·5–15·0)		Murphy, Clark, and Flippin (1943)
Sulphaguanidine	1–7 g.	1·5–4·0*		Marshall, Bratton, *et al.* (1940)
Succinyl sulphathiazole	17 g. followed by 3 g. 4-hourly	0·5–1·0 (sulphathiazole)	1·0–2·0 (succinyl sulphathiazole)	Poth and Knotts (1942)

* Blood concentration at about 4 hours after single dose is taken.

Solubilities of Sulphonamide Compounds

The solubilities of the various sulphonamide compounds and their acetyl derivatives are often important. A table of the relevant data is given in M.R.C. War Memorandum No. 10, "The Medical Uses of Sulphonamides," to which reference should be made. Briefly summarized, the compounds may be classified as: (*a*) relatively highly soluble (>200 mg. per 100 c.cm. at 37° C. and *p*H 7.4)—sulphanilamide, sulphaguanidine, sulphacetamide, sulphadimethylpyrimidine, and acetyl-sulphanilamide; (*b*) moderately soluble (50–200 mg. as above)—sulphathiazole, sulphamerazine, acetyl-sulphaguanidine, and acetyl-sulphadimethylpyrimidine; and (*c*) poorly soluble (<50 mg. as above)—sulphapyridine, sulphadiazine, acetyl-sulphapyridine, acetyl-sulphathiazole, and acetyl-sulphadiazine. The solubility of almost all sulphonamides is greatly increased by making the solution alkaline. The sodium salts of the sulphonamides are extremely soluble, up to one part in three.

Action on Various Organs

Examined by the methods of classical pharmacology, sulphonamides are comparatively inert, and sulphanilamide has no effect upon intestine, uterus, heart, or blood pressure. Given in toxic doses to laboratory animals, it depresses the cerebral cortex and excites subcortical centres, producing coma followed by a condition resembling decerebrate rigidity (Hawking, 1937; Marshall, Cutting, and Emerson, 1938). Similar symptoms of convulsions and rigidity (followed by recovery) have occurred in a 3-year-old child who took 6 g. sulphanilamide (Reed, 1944). A case has also been recorded (Cutts and Bowman, 1941) of a man who was given by mistake 30 g. sodium sulphapyridine during a 10-hour period. The main nervous symptoms were restlessness, vomiting, and hiccup, but no convulsions, twitching, or loss of mental lucidity. When monkeys are given repeated sublethal doses of sulphapyridine or sulphathiazole a characteristic symptom-complex is produced, consisting of anorexia, increasing nausea with or without vomiting, and diarrhoea. The commoner toxic effects which occur in man are too well known to require detailed description. They may be classified as: irritation of alimentary canal (nausea and vomiting); effects on blood cells and bone marrow (haemolytic anaemia, agranulocytosis, thrombocytopenia); effects on blood pigments (cyanosis, methaemoglobinaemia, sulphaemoglobinaemia); sensitization phenomena (drug fever, skin rashes); degeneration of particular organs (jaundice and liver damage, peripheral neuritis); and effects on the brain (mental depression, headache, and dizziness).

Effect on Acid–Base Balance

Sulphanilamide tends to cause a shift in the reaction of the body fluids towards the acid side, bicarbonate being lost from the blood. It has been shown that this effect is primarily due to the renal excretion of more bicarbonate (i.e., the kidney cells reabsorb less bicarbonate from the glomerular filtrate as it flows down the tubules) (McChesney, Sprague, and Marshall, 1941; Höber, 1942); while the hyperpnoea and loss of carbon dioxide from the lungs is a secondary compensation. Accordingly, this effect can be corrected for clinical purposes by giving sodium bicarbonate in doses equal to those of sulphanilamide. There is some evidence that this action of sulphanilamide may possibly be connected with the ability of the drug to inhibit carbonic anhydrase, the enzyme which catalyses the liberation of carbon dioxide from the carbonate of the plasma; as was shown by Mann and Keilin (1940), this enzyme is strongly and reversibly inhibited by sulphanilamide, but not by sulphonamides in which substitutions have been inserted on the —$SO_2.NH_2$ group; e.g., sulphathiazole. A blood concentration of 3–4 mg. sulphanilamide per 100 c.cm. does not affect the excretion of carbon dioxide from the lungs in men at rest; but in exhausting exercise there is some hindrance, and men taking 2–3 g. sulphanilamide daily are handicapped mentally and physically when required to perform exacting or strenuous work (Roughton, Dill, Darling, Graybiel, Knehr, and Talbott, 1941). On the other hand, men taking 2–4 g. sulphathiazole or sulphadiazine are not handicapped in this way (Roughton, Darling, Forbes, Horvath, Robinson, and Talbott, 1942).

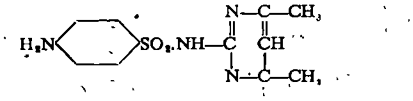
Other Actions

Sulphapyridine has some antipyretic action, which may partly account for the rapid fall of temperature which it causes in patients with pneumonia (Nicolai, 1941). The action of sulphonamides on isolated tissue cells, and their behaviour when applied locally to wounds, have been reviewed by Hawking (1943). Briefly, saturated solutions of the more soluble sulphonamides—e.g., sulphanilamide—have an injurious effect upon cells in tissue culture, but concentrations of less than 50 mg. per 100 c.cm. are usually harmless. When applied to wounds, sulphonamides probably cause slight harm to the tissues, but this is quite trivial compared with that caused by the unchecked growth of bacteria.

When rats are placed on purified diets containing sulphaguanidine or succinyl sulphathiazole (which suppress the growth of the coliform bacilli of the large intestine) growth is diminished and various pathological lesions are caused—e.g., aplasia of the bone marrow, hyaline sclerosis of blood vessels and viscera, dermatitis, and hypertrophy of the thyroid gland. It is considered that these effects are probably due to lack of substances, such as folic acid, which are synthesized by the bacteria of the large bowel (Ashburn, Daft, Endicott, and Sebrell, 1942; Black, Overman, Elvehjem, and Link, 1942; Mackenzie, Mackenzie, and McCollum, 1941).

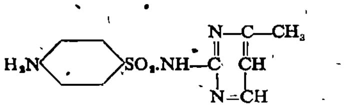
Notes on the Pharmacology of Some Newer Sulphonamides

Sulphadimethylpyrimidine (sulphamezathine): [2(*p*-aminobenzene-sulphonamido)-4: 6-dimethylpyrimidine].



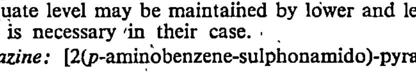
Synthesized by Sprague, Kissinger, and Lincoln (1941), and by others, and introduced (as sulphamethazine) for clinical use by Macartney *et al.* (1942). More soluble than sulphadiazine or sulphamerazine. Rapidly absorbed from the intestine, but slowly excreted, so that a high blood concentration can be produced by moderate dosage. When 4 g. is given by mouth for pneumonia, followed by 2 g. every 6 hours (or 1 g. every 4 hours), the blood concentration of free sulphonamide reaches 8 mg. per 100 c.cm. in 1–3 hours and the subsequent blood level ranges from 2 to 13 (average 6) mg. per 100 c.cm. The total recovery in the urine is usually about 50% of the amount ingested. Judged according to equal blood concentrations, the toxicity and therapeutic potency are similar to those of sulphadiazine. Although both sulphadimethylpyrimidine and its acetyl derivative are comparatively soluble, one case of haematuria and one of urinary suppression occurred in a series of 77 patients (Peters and Easby, 1943). However, renal symptoms are usually rare with this compound.

Sulphamerazine: [2(*p*-aminobenzene-sulphonamido)-4-methylpyrimidine].



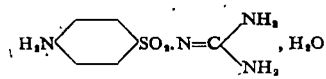
Sulphamerazine has recently been described at length in this *Journal* (Feb. 3, 1945, p. 155), so that repetition here is unnecessary. In brief, sulphamerazine is intermediate in solubility between sulphadiazine and sulphadimethylpyrimidine; its activity and toxicity, measured in terms of blood concentration, are similar to those of these two compounds; it is rapidly absorbed and produces a more persistent high concentration in the blood than either of them, so that an adequate level may be maintained by lower and less frequent dosage than is necessary in their case.

Sulphapyrazine: [2(*p*-aminobenzene-sulphonamido)-pyrazine].



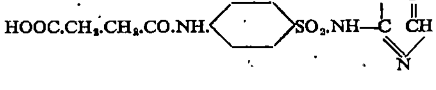
Small doses of this compound lead to a relatively high blood concentration, while large doses cause no corresponding increase. Consequently, at a low dose lovel sulphapyrazine is more active than other sulphonamides, but at a high dose level this advantage disappears. Absorption is somewhat irregular, making its therapeutic effect uncertain; this irregularity would be a handicap for clinical use. As absorption in the intestine is incomplete, large proportions of the ingested dose reach the faeces, and this compound would therefore seem to be suitable for the treatment of bacillary dysentery; but no clinical reports have yet appeared about its use for this condition (Ruegsegger, Hamburger, Turk, Spies, and Blankenhorn, 1941; Schmidt and Sesler, 1943; White, 1942).

Sulphaguanidine: [*p*-aminobenzene-sulphonyl-guanidine].



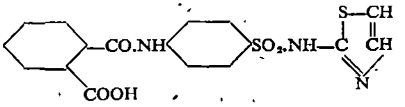
Sulphaguanidine is poorly absorbed when given by mouth, and a considerable portion appears in the faeces, this being the reason which led to its use in the treatment of bacillary dysentery. After doses of 1–7 g. per 70 kg. man, the blood concentration (free) is about 1.5–4 mg. per 100 c.cm., the peak occurring after approximately 4 hours; about 25–30% of the compound in the blood is acetylated. The proportion excreted in the urine after a single dose of 1–7 g. is 10–60%, of which two-thirds are free and one-third is acetylated (Marshall, Bratton, *et al.*, 1940). After a course of 9 g. during 24 hours to a patient, 1.3 g. was recovered from the faeces and 3.1 g. from the urine in 48 hours (Hawking, 1942a). Penetration into the cerebrospinal fluid is low. In dehydrated patients with dysentery in the British Army in Egypt, sulphaguanidine has occasionally caused blockage of the urinary passages. (See also Hawking, 1942b.)

Succinyl sulphathiazole (sulphasuxidine): [2-(*p*-succinyl-amino-benzene-sulphonamido)-thiazole].



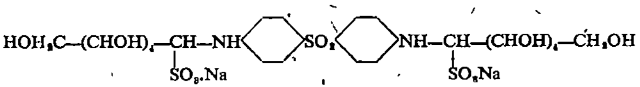
This compound, which was introduced by Poth and Knotts (1941), is broken down in the intestine, liberating small amounts of sulphathiazole; the growth of the coliform bacilli (but not that of the streptococci) in the large intestine is thereby suppressed and the faeces become semi-fluid and odourless; about 2–4 motions are passed daily. The compound is recommended for dysentery and for the preparation of patients before undergoing operations on the large intestine. The standard dosage in man is 0.25 g. per kg. initially and 0.04 g. per kg. 6 times daily for maintenance. The urine contains about 5% of the total dose administered. The blood contains about 0.5–1.0 mg. free sulphathiazole per 100 c.cm. and 1.0–2.0 mg. total (i.e., acetyl-sulphathiazole plus succinyl sulphathiazole) (Poth and Knotts, 1942; Poth, 1942).

Phthalyl sulphathiazole (sulphathalidine): [2-(*p*-phthalyl-amino-benzene-sulphonamido)-thiazole].



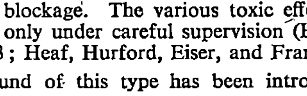
Introduced by Poth and Ross (1943, 1944) and Kirchhof, Racely, Thompson, and David (1943). It closely resembles succinyl sulphathiazole, but is 2–4 times more active in suppressing the growth of coliform bacilli in the intestine, and it renders the faeces less fluid.

Promanide (U.S.A.: promin): [Sodium salt of *p-p'*-diamino-diphenyl-sulphone-N,N'-di(dextrose sulphonate)].



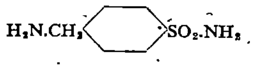
Introduced by Feldman, Hinshaw, and Moses (1940) for the treatment of tuberculosis. It restrains the development of experimental tuberculosis in guinea-pigs, although it does not save all the animals. In human pulmonary tuberculosis it appears to exert a definite slight beneficial effect, but this is balanced by the production of toxic symptoms. It has now been given to several hundred patients. The daily dose is about 1.6 g. (up to 3.2 g.), and this has been continued as long as 6 months. The average blood concentration on this dose is about 2.4 mg. per 100 c.cm. Promanide enters the cerebrospinal fluid only in low concentration. The chief toxic symptoms are diminution of haemoglobin and of erythrocytes in the blood (apparently due to haemolysis), cyanosis, and gastro-intestinal disturbances; rashes, headache, agranulocytosis, and other symptoms have also been reported. It is excreted in the urine (average concentration about 100 mg. per 100 c.cm.), but being soluble it does not cause urinary blockage. The various toxic effects indicate that it should be given only under careful supervision (Hinshaw, Pfuetze, and Feldman, 1943; Heaf, Hurford, Eiser, and Franklin, 1943).

Another compound of this type has been introduced recently—viz., *promizole*.



This is similar in its properties to promanide, but is probably more active and less toxic.

Marfanil (mesudin, homosulphanilamide, sulphamylon): [*p*-amino-methyl-benzene-sulphonamide].



Introduced by I. G. Farbenindustrie, tested biologically by Domagk, and described by Klarer (1941). It had also been prepared independently by Miller, Sprague, Kissinger, and McBurney (1940). It differs from all the other sulphonamides in that the amino group (H_2N) is separated from the benzene ring by a methyl (—CH_2—) group. Accordingly it is not diazotizable and cannot be estimated by Marshall's method. Also, it is not inhibited by *p*-aminobenzoic acid. Marfanil-fast strains of bacteria are not resistant to sulphathiazole, and conversely (Link, 1943). Apparently the receptor of the organism on which it acts is different from that which is susceptible to the usual sulphonamide action. It is more soluble in water than sulphanilamide (1,970 mg. per 100 c.cm. at 37° C.), and very soluble in dilute acids or alkalis. It is less active than sulphanilamide against streptococci. Domagk (1942) claims that it is much more active against anaerobic infections than this compound; but this claim is not confirmed by Schreus, Brauns, and Schümmer (1941). It seems to be used extensively in the German army for local application to wounds as marfanil-prontosil powder (i.e., 1 part marfanil, 9 parts sulphanilamide), and since it is not inhibited by *p*-aminobenzoic acid it may have real advantages for this purpose. Mitchell, Rees, and Robinson (1944) have recently described a clinical trial for use as a local application to infected wounds; they consider it valuable for this purpose. Their trial was made with German material captured at El Alamein (see also *Lancet*, 1944, **1**, 635)

INVESTIGATION AND RESULTS OF TREATMENT OF 1,000 CASES OF VAGINAL DISCHARGE

BY

OSWALD LLOYD, M.D., F.R.C.S., M.R.C.O.G.

Assistant Gynaecological Surgeon, Addenbrooke's Hospital, Cambridge; Late Gynaecological Registrar, Middlesex Hospital

The following account embodies the results of the investigation and treatment of 1,000 women complaining primarily of vaginal discharge. Each was carefully interrogated and all necessary bacteriological and serological investigations were made. Details of clinical examination and findings are purposely omitted, as the routine is now well established. The cases were all directly under my care for a period of at least six months. The services of a trained nurse were at all times available, and this has contributed greatly to the excellence of the end-results. The case incidence of the various types will be found in the Table, and each group will be briefly discussed and conclusions drawn from the results.

Case Incidence

(*a*) Trichomonas vaginitis	447
(*b*) Gonococcal infection	178
(*c*) Combined trichomonas vaginitis and gonococcal infection	32
(*d*) Residual and non-specific erosions	193
(*e*) Monilia vaginitis	57
(*f*) Vulvovaginitis of infancy	14
(*g*) Senile vaginitis	41
(*h*) Non-inflammatory leucorrhoea	27
(*i*) Polypi, neoplasms, and foreign bodies	11
Total	1,000

(a) Trichomonas Vaginitis

The literature dealing with this condition is considerable. At first there seemed to be some doubt as to the pathogenicity of the organism, but now it is widely accepted as capable of producing a vaginitis—acute, subacute, and chronic. The primary source of the infection is still debated: the rectum is a potential origin, but is by no means definitely incriminated. Almost all cases occur during the reproductive period, but this series includes one pre-pubertal and four post-menopausal. It affects undoubted virgins and has a predilection for the vagina in pregnancy. The association of gonorrhoea and trichomonas vaginitis in 32 cases draws attention to the need for careful exclusion of Neisserian infection even if *Trichomonas vaginalis* has been demonstrated. The following method of treatment has yielded the best results, both immediate and remote.

As soon as diagnosis is established, one stovarsol vaginal compound tablet is inserted daily for at least eight weeks, including during the menstrual period. Once a week the vagina is thoroughly irrigated with sodium bicarbonate solution, one drachm to the pint, then dried, and finally swabbed out with half-strength Bonney blue solution. This must be done at least once during two consecutive menstrual periods. At the conclusion of the eight weeks the patient is given enough tablets to insert one daily during the next three menstrual periods. The vaginal painting can with advantage be done once a week. Certain modifications have to be made in individual cases; for example, when the hymen is intact the Bonney blue solution is run in through a small rubber catheter. During pregnancy an arbitrary time period of eight weeks has been adopted.

One case of trichomonas vaginitis deserves special mention, because it was among the first few in the series, and it remains after five years the only one that has resisted all efforts to dislodge the causative organism.

The patient, then aged 30, had had an irritating discharge for several months. The only positive laboratory finding was *Trichomonas vaginalis*. She was treated with 5% negatol vaginal packs—a method then being used by me, and reported in the *Lancet* in 1939. This failed, and in company with many others she was insufflated with silver picrate. Moderate success attended this treatment; a number were cured, but recurrences were not infrequent, and this patient was among them. She was then given a full routine treatment as outlined above, and obtained several weeks' freedom from discharge; but once more it recurred. In addition she complained that her periods were profuse and irregular. Little improvement was obtained by medicinal measures, and curettage on two occasions brought only temporary relief. Accordingly, subtotal hysterectomy was carried out. The *Trichomonas* infection continued to thrive after discharge from hospital, and the patient was readmitted. The cervical canal was cauterized and the vagina lightly packed with gauze soaked in half-strength Bonney blue solution; this was removed after 12 hours, and douches of flavine 1 in 1,000 were given three times a day. In addition stovarsol vaginal compound was inserted daily into the rectum, and the urethra was swabbed with 10% protargol. After six weeks' treatment the patient was sent home, only to return in three weeks with a typical acute *Trichomonas* infection.

She was advised to douche three times a day and to "grin and bear it." This she did for several months; then she once more appealed for help. She was readmitted to hospital and given a full course of 40 g. of prontosil album, without benefit. This was followed by a course of stilboestrol up to 5 mg. a day for six weeks, without tangible improvement. The vagina was packed with gauze soaked in 5% N.A.B. paint for three weeks; after this improvement occurred and hopes ran high. She left the hospital with the vagina looking normal for the first time in three years. Recurrence was noted in less than a month, and a repetition of the N.A.B. led to local soreness and had to be abandoned. She was once more admitted; the vagina was irrigated with a solution of quinosan and she was given a course of quinosan by mouth. Relief was only temporary, and she remained infected in spite of all the above treatments.

(b) Gonorrhoea

This review serves to illustrate that gonorrhoea is far from being the commonest cause of discharge in women. The diagnosis in earlier cases was made by smears only, but, on the recommendation of the American Neisserian Society, cultures of the cervical pus were made. This is said to lead to more positive diagnosis, but in the present series positive cultures were obtained only if positive smears had been reported.

Treatment in the first year was by the routine administration of 40 g. of prontosil album by mouth, daily douches, high vaginal packs of gauze soaked in glycerin, and urethral swabbing with 10% protargol. The prontosil album was replaced by sulphapyridine, and this eventually by sulphathiazole. Local treatment was discontinued, but 5 g. of prontosil album powder was insufflated into the vagina twice within the first week. In 203 cases the gonococcus could not be demonstrated after the conclusion of the treatment, but 7 were still positive, and recourse was had to local treatment as previously described. This was continued until two post-menstrual smears were negative following the use of a provocative vaccine.

Groups c and d

Combined gonococcal and Trichomonas infections were treated with sulphonamides by mouth, and locally by means of stovarsol and Bonney blue. The results were satisfactory in all cases.

Treatment of *residual and non-specific erosions* was by application of pure negatol to the eroded area twice weekly. The results were satisfactory for small erosions, but larger erosions required electric cauterization.

(e) Monilia Vaginitis

This group deserves wider recognition, and will be discovered more often if search is made. In a typical case the vaginal mucosa is covered with the white patches characteristic of *Oidium albicans*. The predominant symptom is a white musty-smelling discharge causing much irritation. The first treatment adopted was douching, followed by painting of the vaginal walls with 2% gentian violet at intervals of a few days. This yielded fair results, but was varied in an attempt to find a completely satisfactory method. Monsol (1/200) douches were equally satisfactory, but the best treatment, and the one used solely during the past year, was the local application of mersogel fungicidal jelly (Glaxo). The patient attended the clinic for treatment, to ensure that the fungicide reached the upper vagina. The results were very satisfactory; the average duration of treatment was three weeks. The infection is apparently more common during pregnancy.

(f) Vulvovaginitis of Infancy

The number of cases of this disease is small, but the results were excellent. Each patient was admitted to hospital and examined under anaesthesia. Material was obtained for smears and culture, after which the vagina was irrigated with a bland lotion; finally a few c.cm. of 10% argyrol were instilled into the vagina, and the child kept recumbent, with the foot of the bed on blocks. Sulphonamides were given to all these patients in doses proportionate to their age, and stilboestrol, 1 mg. t.d.s., was administered for 21 days. The argyrol instillation was repeated after a week. All cases were free from any evidence of infection six weeks from the start of treatment.

Groups g, h, and i

Most cases of *senile vaginitis* presented in a typical fashion —thin purulent discharge causing irritation of the vulva, with punctate haemorrhages appearing on the vaginal walls. Treatment was by lactic acid douches and the administration of stilboestrol by mouth in doses averaging 3 mg. a day. The results were eminently satisfactory in all cases, resolution occurring within two months of the beginning of treatment.

Non-inflammatory leucorrhoea is diagnosed by examination of a high vaginal swab, the findings being epithelial cells and Döderlein's bacillus with no pus cells. Such cases are often made worse by ill-advised douching with various antiseptics. Relief was obtained by the use of sodium bicarbonate solution, but the very nature of the complaint precludes complete cure.

Group i requires no discussion. Treatment was by the usual methods.

Conclusion

This account is incomplete in that no attempt has been made to give detailed figures of each subsection of each group; but such details would produce a maze of figures that would only bore and confuse. The object has been to give as briefly as possible my own methods and conclusions, in the hope that they will help others engaged in dealing with similar problems.

I wish to acknowledge with gratitude the help given by the Bland-Sutton Institute of Pathology and the Pathological Department of Addenbrooke's Hospital, and, in particular, that given by the nurses who carried out the treatment in the clinic.

A Polish Military Hospital in the Middle East is now equipped with a laboratory for making penicillin, and is the only military place in the Middle East for making this drug. Prof. Odrzywolski is in charge of the manufacture. The first two phials of mould were sent to the Polish Hospital by Sir Howard Florey in May, 1944. The Poles have carried out their own experiments, and Prof. Odrzywolski came to England recently to visit one of our chief penicillin research centres, in order to exchange scientific information and learn improved methods. The Polish Hospital in the Middle East supplies not only other Polish hospitals but other Allied military medical institutions in the Middle East.

TREATMENT OF EPILEPSY BY ELECTRICALLY INDUCED CONVULSIONS

A PRELIMINARY REPORT*

BY

GERALD CAPLAN, M.B., Ch.B., B.Sc., D.P.M.

Deputy Medical Superintendent, Cefn Coed Hospital, Swansea

Modern views on epilepsy lay stress on an underlying cerebral dysrhythmia as being the essential feature of the disease. This disturbance of the electrical equilibrium of the brain leads to the occasional accumulation of an excessive quantity of energy, and the epileptic fits can be regarded as a discharge mechanism whose function it is to disperse this energy whenever it exceeds a certain threshold value.

An epileptic's chief disability lies in the fact that his fits are rarely predictable, and may occur at any awkward moment or in situations involving considerable danger. The idea has therefore been developed of replacing these spontaneous fits by electrically induced convulsions which can be produced under controlled conditions of time and place. It is not intended that this therapy should supersede the pharmacological methods of combating the fits, but rather that it should be an accessory treatment in those cases in which fits occur despite full dosage of anticonvulsant drugs. The present paper is a preliminary report on the results of an investigation being undertaken in Cefn Coed Hospital. Publication at this early stage has been decided upon in order to stimulate criticism and to interest other workers in the subject.

Material.—Fifteen male epileptics have been under treatment for periods ranging from three to nine months. One is an out-patient, and has been in regular employment during the last six months. The others have been chosen from among the in-patients of this public mental hospital. The only factors governing the choice were that they should be having at least 2 to 3 fits a month despite full doses of anticonvulsants, and that they should be in good general physical condition. Nine cases are being treated with phenobarbitone, five with epanutin, and one with a combination of both drugs. All the in-patients are suffering from psychosis associated with the epilepsy; five are voluntary patients and the rest are certified.

Technique.—The convulsions are electrically induced before breakfast either once or twice a week. The frequency is varied according to the reactions of the individual patient, and no general rule as to the optimum has as yet been formulated. The apparatus in use is a simplified lightweight machine which has been built to my design by Mr. E. L. Turner, a Swansea radio engineer. It has a range of 35 to 135 volts, and the time switch can be set to limit the current to from 0.1 to 0.5 second. The output has varied between 0.25 amp. and 1.3 amp. This machine has been found to be perfectly safe and reliable, and because of its handy size is very easy to use. Large numbers of patients can be treated rapidly at the same session—the 15 epileptics can be treated comfortably in 20 minutes. In all cases except one the usual pharmacological treatment has continued unchanged.

The Convulsion.—The induced convulsion is ushered in by a sudden mass flexion movement, which coincides with the passage of the electric current, and is probably produced by the local stimulation of the cortical cells. This is followed by the usual tonicclonic seizure, the details of which vary from patient to patient: one man flings his arms outwards in the tonic phase, another throws them forwards; the fingers in one case are extended, in another they are flexed into a claw shape, etc. The picture of the tonicoclonic episode is an unvarying one in each individual patient, and is exactly the same as his behaviour during a spontaneous epileptic fit. The seizure is followed by a short period of coma with stertorous breathing, and this leads on to a stage of confusion lasting from 5 to 30 minutes. The last stage is usually of shorter duration than that occurring after an epileptic fit, and is rarely accompanied or followed by headache.

Illustrative Case Records

Case 1.—B. I., a merchant seaman aged 25, under treatment as an out-patient, has suffered from epilepsy for 4 years. He had received all the usual pharmacological treatment, and had lately been on epanutin 1½ gr. b.d., and pot. brom. 20 gr. t.d.s. Despite this treatment he had never suffered less than an average of 5 grand-mal fits a month. His fits usually came on in the mornings, and were followed by headache and drowsiness, which incapacitated him for the rest of the day. On March 29, 1944, electrical convulsion treatment (E.C.T.) was started, and he was given a convulsion once a fortnight. His fits immediately ceased; and he did not have one until April 22. He had a second fit a month later. The convulsions were then increased to once weekly, and since June 30 he has been coming up to the hospital every Friday morning for treatment, and leaving an hour afterwards to go back to work. He had given up his work as a seaman because of the frequent fits, and shortly after starting electrical treatment he had obtained employment as a builders' labourer, which job he has kept. His bromides were gradually cut down and then discontinued, but the epanutin has been carried on. In the last 6 months he has had 3 further fits, but they have not been followed by the usual post-epileptic confusion and headache. The patient himself is delighted with the treatment. He has regained his self-confidence, and has recovered from the depression and hopelessness into which his disability had precipitated him.

Case 2.—O. P., a tin-worker aged 45, was admitted as a certified patient on July 4, 1942. He has suffered from epilepsy since 1919. On admission he was confused, restless, suspicious, and violently combative. He quieted down within a few weeks, but had remained irritable and quarrelsome, interfering and complaining, and liable to sudden outbursts of violence. He was treated at first with sodium phenobarbitone 1 gr. t.d.s., and since March 9, 1943, with epanutin 1½ gr. t.d.s., but his fits had averaged 6 grand-mal attacks a month. On Aug. 29, 1944, he began electrical treatment, and since that date has had only 2 spontaneous fits. He was started with a convulsion once weekly, and later this was increased to two a week. His behaviour has greatly improved; he is now friendly and no longer aggressive, his irritability has disappeared, he is working well in the ward, and is going out regularly on visits to his relatives, who report that his conduct outside is exemplary.

Case 3.—M. T., a tin-plate worker aged 30, was admitted as a voluntary patient on Sept. 14, 1943. He is a feeble-minded man who has suffered from epilepsy since 1942. On admission he was dull and confused, incontinent of urine, dirty and untidy in dress, and barely volitional. He deteriorated rapidly, and, having lost volition, was certified on Nov. 15, 1943. Since then he had remained more or less unchanged—dirty, untidy, asocial, unoccupiable, and depraved in habits. He had been treated with phenobarbitone 1 gr. t.d.s., but had averaged 9 grand-mal fits a month. He began E.C.T. on Aug. 22, 1944, and since then has had a total of 10 spontaneous fits—i.e., an average of 2 a month. He began his treatment with one convulsion a week, and on Sept. 13 this was increased to two a week. His behaviour has improved out of all recognition. He has become clean and tidy; he has begun to converse, though only in a simple manner; he is working well in the ward and showing some initiative; and his former irritability has disappeared.

Case 4.—C. A., a colliery labourer aged 42, was admitted as a certified patient on April 25, 1933. On admission he was clearly orientated, but showed a considerable amount of retardation. His behaviour was fairly good, but he was subject to sudden attacks of irritability and combativeness. With the passage of time he had become more dull and retarded, and his periods of quarrelsomeness and violence had increased in severity and in frequency. He took little interest in his surroundings, and refused to do any work. He was treated with sodium phenobarbitone, 1 gr. t.d.s., until March 9, 1943, when this was changed to epanutin 1½ gr. t.d.s. He had averaged 4 grand-mal attacks a month during most of his period in hospital. He was put on E.C.T. on Aug. 29, 1944, and since then has not had a single major fit. He started treatment with one convulsion a week, and when this was increased to twice weekly he began to develop some confusion, so he was put back to his previous dose, and the confusion has cleared. His behaviour remains exactly the same as previously.

Results

Table showing Effect of E.C.T. on Frequency of Fits

Patient:		B. I.	O. P.	M. T.	I. H.	E. C.	C. A.	C. W.	W. W.	W. M.	A. N.	E. B.	J. H.	A. W.	J. M.	R. S.
Average number of grand-mal fits in a month	Before E.C.T.	5	6	9	3·5	4	4	2	8	4	4	3	2·5	14	2	9·5
	Since E.C.T.	0·5	0·5	2	1	1·5	0	0·25	3	3	1·5	2·3	0·8	14	0	9

Effect on the Fits.—Eleven patients have shown a marked reduction in the frequency of their grand-mal attacks. In the other four cases there has been no great change. The fits, in addition to being less frequent, seem in many cases to be less severe, though this is of course only a clinical impression based

---

* Received for publication Dec. 26, 1944.

on the testimony of the nursing staff. Certainly there has been some improvement in the length and intensity of the post-epileptic confusion, and this has been very pronounced in five cases. Only one patient in the series suffers to any great extent from minor fits, and these have shown a definite reduction since starting treatment.

Effect on Behaviour.—All the in-patients are severe psychotics of poor prognosis, who have been a constant source of worry to the nursing staff. The effect of the new treatment on their behaviour has been very interesting. Seven of them have shown no change, but in the others there has been a remarkable and welcome improvement. They are less irritable and quarrelsome, they are no longer liable to outbursts of violence, they have become less confused and more co-operative, and they are taking more interest in the ward and have become useful workers. One patient used to have frequent furors, but these have now ceased. One patient suffers from psychic equivalents which take the form of periods of aggressiveness and bad temper lasting several hours, and which are not controllable by means of drugs. Since starting E.C.T. five months ago he has had only one of these attacks, and this was immediately terminated by a single convulsion, induced as an emergency measure.

Complications

No severe or alarming complications have so far been experienced.

Increase in Frequency of Fits.—In four cases there was an increase in the frequency of fits on beginning the electrical treatment, but this did not last longer than the first month, and was followed by a reduction in number.

Increase in Confusion.—In a few cases the patients have gradually become more confused, especially when being given treatment twice weekly. This confusion always disappeared when the number of induced convulsions was subsequently decreased.

Discussion

Kalinowsky and Kennedy (1943) have reported on the value of artificial convulsions as a means of breaking up an epileptic cloudy state. During the course of their investigation on the electrical convulsive threshold of epileptics they were successful in keeping two patients free from fits for some months by induced convulsions, but were of the opinion that "no practical value can be attributed to such a procedure." Robinson (1943) has reported a case of psychosis of a schizophrenic type in an epileptic girl which was improved as a result of two short courses of E.C.T. Her fits were not decreased by the treatment.

Apart from these papers the literature contains no direct references to the value of E.C.T. in epilepsy. The idea of replacing epileptic fits by electrically induced convulsions as a therapeutic measure is therefore a new one; but the preliminary results of the present investigation show that it is not without promise, and that the method is one which merits further study.

A problem which immediately arises is that of choosing the right type of case for the treatment. The material on which the present study is based is obviously not very suitable, consisting as it does mainly of demented psychotics. It would be interesting to investigate the effect of the convulsions on more out-patients of the type of Case 1, especially those who show some definite rhythm in the periodicity of their fits. On the other hand, a treatment which helped to diminish the irritability and aggressiveness of epileptic psychotics would be very useful if criteria could be laid down as to the type of patient likely to benefit.

A second problem to be solved is whether the treatment has any lasting effect and so can be given in short courses, or whether its results are so transient that it must be given continuously as a form of "replacement therapy."

Many other problems present themselves for solution, and it is hoped that some of them may be made the subject of future communications.

Summary

The possibility is suggested of replacing epileptic fits, which may occur anywhere at any time, by convulsions electrically induced under controlled conditions of time and place.

The treatment of 15 cases of epilepsy by this method is described and a preliminary report is made on the results.

In 11 cases the fits have been materially diminished.

In 7 cases the symptoms of an associated psychosis have been ameliorated.

The value of an induced convulsion as a means of terminating a dangerous psychic equivalent has been illustrated.

No serious or alarming complications have been experienced.

My best thanks are due to Dr. N. Moulson, medical superintendent, for his help and advice; and to Mr. W. Place, Mr. L. J. Cole, and the male staff of Cefn Coed Hospital for their invaluable assistance.

FRACTURES OF THE ZYGOMA BONE

BY

B. ELIZABETH NESBITT, M.B., Ch.B., B.Sc., F.R.C.S.Ed.

AND

C. R. DUNCAN LEEDS, M.B., Ch.B., F.R.C.S.Ed., D.O.M.S.

Fractures of the zygoma or malar bone are always due to direct violence, the direction of violence determining the displacement. The bone is usually driven backwards and medially into the maxillary antrum and impacted there. The fracture is often comminuted and may have extension along the floor of the orbit into the orbital plate of the maxilla.

The zygomatic bone is a strong bone resting on four fragile supports, one or more of which are the sites of fracture, where it unites with: (1) The maxilla directly above the infraorbital foramen, the two bones forming the inferior orbital margin. (2) The zygomatic or lateral angular process of the frontal bone, forming the lateral margin of the orbit. (This margin is, in rare cases, cut by a second suture where the malar bone consists of two pieces—"mala bipartita" or "os japonicum" (Whitnall).) (3) The zygomatic process of the temporal bone forming the zygomatic arch. (4) The anterior wall of the maxillary antrum.

Diagnosis

Diagnosis can often be made at sight. Many or all of the following signs and symptoms are present: (1) "Black eye," subconjunctival haemorrhage; (2) unilateral epistaxis; (3) flattening of contour and lack of expression on the affected side (depression may be masked by oedema and ecchymosis); (4) irregularity and depression of the inferior orbital margin, or zygomatic arch just anterior to the ear; (5) pain and tenderness over one or more of supports previously mentioned; (6) pain on and difficulty in mastication; (7) numbness in the region supplied by the infraorbital nerve; (8) mobility and crepitus usually absent.

Confirmation is made by radiographs, the chin–nose position being the most suitable in our experience; this reproduces the orbital margins and any irregularity very clearly, although Stone recommends a mento-vertex view, which shows up the zygomatic arch and any inward displacement of the zygoma. The degree of violence may be almost insignificant and the fracture missed.

Complications

Ocular.—Persistent and vertical diplopia, due to (*a*) lack of support of the floor of the orbit, or (*b*) damage to the ligament of Lockwood (ligamentum suspensorium oculi), the eyeball being displaced downwards, with consequent hypotropia or hypophoria, or (*c*) orbital haemorrhage and organization of the clot interfering with the action of the inferior oblique and inferior rectus muscles, or (*d*) injury to the nerve supply of these muscles.

Nasal.—Infected haematoma of the maxillary antrum necessitating drainage.

Others.—Permanent loss of sensation in the region supplied by the infraorbital nerve. Mechanical obstruction to jaw movements due to pressure of in-driven fragments of the zygoma in the coronoid process of the mandible.

Treatment

Early replacement of fragments is essential to ensure complete absence of complications. The method of choice we consider to be the Caldwell-Luc approach to the antrum through an incision in the gingival sulcus. The line of fracture or the comminuted fragments, are visible in raising the cheek. All loose fragments should be removed and also the residual blood-clot. The impacted bone is freed and raised upwards and outwards and the inferior orbital margin reconstituted. The antrum is packed with gauze, impregnated with bipp, and the end brought through an opening into the inferior meatus. The incision in the mouth is closed. The pack is removed in five days and the patient allowed home in 10 to 14 days.

Other Methods of Replacement.—(1) Gillies recommends an incision in the scalp above and anterior to the ear through skin and temporal fascia. A long, narrow, curved elevator is slid downwards behind the zygomatic arch and the bone elevated upwards and outwards. He admits that comminution requires the radical antrum approach. (2) Spaeth recommends pressure outwards on the lower part of the lateral orbital margin below the outer canthus. (3) Others recommend pressure from within the mouth or the use of hooked forceps through an external incision.

We do not think that enough power could be exercised in badly impacted cases using these methods. The ocular complications in untreated cases with vertical diplopia may be dealt with by suitable operations on one or more of the extrinsic ocular muscles, usually a weakening of the action of the contralateral synergist, with subsequent orthoptic treatment if required. As a last resort, prismatic lenses to restore the muscle balance may be prescribed. Where the antrum has been opened and drained no subsequent complication has followed in our cases.

Case Histories

Case 1.—A. S., aged 18. 10/7/42: Fell off motor-cycle; severely injured. Fractured right zygoma missed. 1/10/42: Vertical diplopia; impaired action of right inf. oblique; 24 prism dioptres hyperphoria; left eye higher than right (L./R. 24Δ. 8/10/42: Operation—recession of left sup. rect. muscle. Three weeks later still some diplopia. 16/11/42: Operation—myectomy of left inf. obl. 16/12/42: Hyperphoria L./R. 2Δ.; no diplopia; visual acuity, 6/6 R. and L.

Case 2.—W. T. (59). Knocked down by motor-car, 2/10/42. 13/12/42: Diplopia looking up; fractured left zygoma; impaired action of left inf. obl. ; hyperphoria R./L. 16Δ. 17/12/42: Operation—recession of right sup. rect. 19/1/43: R./L. 4Δ. No further operation desired. Slight diplopia corrected by prismatic lenses.

Case 3.—Mrs. D. (27). 10/3/42: Struck in right eye with fist. 17/3/42: Fractured right zygoma, confirmed by radiograph; fractures at infraorbital foramen and two of lateral wall of orbit, with downward displacement of inferior orbital margin. Treatment refused because of domestic complications. 10/6/43: Diplopia looking down (right inf. rect.), corrected by vertical prismatic lenses. 7/9/43: With glasses, no diplopia; orthophoric with Maddox rod.

Case 4.—T. S. (71). 4/4/43: Fell off bus. Examined 25/4/43: Diplopia down and slightly to left; numb feeling in cheek; epistaxis and subconjunctival haemorrhage at time of accident. Radiograph confirmed fractured zygoma. Reduction refused by patient. Diplopia corrected with 6 prisms vertically, divided between the two eyes. 17/7/43: No diplopia with glasses; prisms reduced to 4Δ; orthophoric with Maddox rod and wing tests. V.A., 6/6 R. and L.

Case 5.—Mrs. C. (54). 17/5/43: Fell in street, sustaining black eye, and subconjunctival haemorrhage. Examined 25/5/43: Fractured left zygoma at infraorbital foramen, with depression of inferior orbital margin. Operation same day; bone easily raised into position and antrum packed. Patient discharged in 10 days. 20/6/43: Perfect position; still numbness of cheek. 17/7/43: V.A., 6/6 R. and L. No diplopia. Maddox rod and wing, orthophoric (no muscle imbalance).

Case 6.—D. M. (56). Struck by fist in right eye. 7/7/42: Several signs present; no displacement; fractured zygoma at infraorbital foramen. No treatment. 28/7/43: V.A., 6/9 R. and L. Maddox rod and wing, orthophoric.

Case 7.—W. F. (57). 10/9/43: Struck on side of face by fall of coal; usual signs present and fractured right zygoma. Impacted fragments disengaged and replaced. 22/9/43: Patient discharged from hospital. 20/11/43: V.A., with glasses, no prisms, 6/6 R. and L. Maddox rod and wing, orthophoric.

Case 8.—T. McA. (18). 3/10/43: Struck by hammer on side of face; usual signs and symptoms. Radiograph confirmed fractured zygoma with extension into orbital plate of maxilla. 10/10/43: Operation revealed comminuted fracture of anterior wall of antrum; fragments removed and zygoma replaced in position. Patient discharged 14 days later. 16/1/44: Radiograph shows perfect alignment; no diplopia; orthophoric.

Case 9.—A. F. (62). 2/11/43: Fell off cycle on left side of face. Many of usual signs present; fractured left zygoma at infraorbital foramen; slight displacement. Operation—bone easily raised into position. Patient discharged in 10 days. 16/1/44: No diplopia; orthophoric.

Summary

Diagnosis and treatment of fractures of the zygomatic bone and its complications are dealt with.

Two cases were not seen early enough; complications treated by extraocular muscle operations.

Seven patients were seen soon after accident, two of whom refused operation; diplopia corrected with prismatic lenses.

Four cases had fractured bone replaced; no complications arose subsequently.

One case required no treatment.

Immediate operative treatment to restore the displacement is stressed. Several methods of reduction are mentioned; open operation by Caldwell-Luc approach is suggested as being the most suitable. Subsequent treatment, operative or optical, of the commonest complication—persistent diplopia—should be carried out at a later date if required.

No patients should be informed that "nothing can be done" for them.

SOLITARY DIVERTICULUM OF THE CAECUM

BY

G. C. DORLING, F.R.C.S.

Department of Surgery, British Postgraduate Medical School, Hammersmith L.C.C. Hospital

The recent report by Dr. Hendtlass (1944) of a case of perforated solitary diverticulum of the caecum has drawn attention to this rare condition, which may be met with when operating for appendicitis. Unless one is aware of the condition it is apt to be mistaken for carcinoma or tuberculosis, and needlessly extensive and severe operations, such as hemicolectomy, may be performed (Grace, 1940).

In 1937 Bennett-Jones reviewed the literature, collecting 19 reported cases and adding 3 of his own. In none of these 22 cases were any associated diverticula of the rest of the colon demonstrated.

The cases appear to be of two types. (1) Congenital true diverticulum of the caecum is an elongated pouch usually arising near the ileo-caecal valve and resembling an extra appendix. (2) False solitary diverticulum of the caecum. This has to be distinguished from the simple non-specific ulcer of the caecum well described by J. R. Cameron (1939) as resembling a peptic ulcer in its pathology. The diverticulum is a definite pouch which may show an area of inflammation in its wall, whereas the ulcer is purely an ulcer without any pouch. From the practical point of view the differentiation is unimportant, for the treatment is the same. The diverticulum is "false" because it does not consist of all the coats of the caecum, as does the congenital type, but is a hernial protrusion of the mucosa and submucosa through the muscularis. This may be caused by pulsion or by traction.

The fact that the diverticulum is usually solitary suggests that it has a different aetiology from multiple diverticulosis of the colon and is against the cause being pulsion from within. I can trace only one case—that reported by Mr. Lawrence Able (1939), in which associated diverticulosis of the pelvic colon was found. Traction may be caused by contraction of the scar tissue of a healing non-specific ulcer of the caecum (cf. diverticula of the duodenum associated with scars of old peptic ulcers).

Three of the reported cases, as well as the one here recorded, were associated with calcified tuberculous mesenteric glands. It is possible that the contracture of scar tissue around these glands may cause the diverticulum by traction. One of the reported cases (Thomsen, 1935) actually showed calcified tissue in the caecal wall. Harold Edwards (1939) calls attention to the comparative youthfulness of these patients with solitary diverticula of the caecum. Eleven of Bennett-Jones's 22 cases were below the age of 32, whereas of Edwards's 15 cases of diverticulosis elsewhere in the colon the average age was 55 years, the extremes being 38 and 75 years.

Treatment.—All that is necessary is to perform a local resection of the diverticulum and adjacent portion of the caecum. A catheter inserted into the caecum through the stump of the appendix, which is usually removed at the same time, is a simple precaution to relieve any tension on the suture line and allow the giving of fluids if necessary.

Case Report

A muscular but not at all obese bricklayer aged 48 was admitted to Lewisham Hospital on March 21, 1939. Two days before admission he began to have pains across the abdomen which settled in the R.I.F. He vomited once the day before admission. There was a history of a right inguinal hernia for three years. Two years ago he had vomiting and general abdominal pain for one week. During the last 18 months he had suffered from vague abdominal pain without any regular relation to meals. He was never completely free from this pain for more than a week. His weight had kept constant.

On admission he resembled a case of acute appendicitis, there being rigidity in the R.I.F., with deep tenderness over McBurney's point. Temperature 98.4° F.; pulse 88; respirations 22. Under general anaesthesia a gridiron incision was made. The appendix was long, contained three faecaliths, but was not inflamed or obstructed. A diverticulum of the infero-lateral aspect of the caecum admitted the tip of the index finger. It was inflamed and very thin at one part. Some calcified glands were seen in the ileo-caecal region. A wedge-shaped portion of caecum including the diverticulum was resected and the caecum sutured in two layers. The appendix was removed and a catheter tied into the caecum through the invaginated stump of the appendix. A corrugated rubber drain was inserted down to the site of resection.

The patient made an uninterrupted recovery. There was a very little faeces-stained discharge from the catheter. The corrugated drain was removed on the fourth day and the catheter on the tenth day. The wound was dry a few days later, and he was discharged home three weeks after admission.

A plain radiograph of his abdomen confirmed the presence of calcified glands in the right lower quadrant of the abdomen. A barium meal showed no diverticula elsewhere in the colon. The barium meal was repeated in March, 1940: again the whole colon appeared normal. He had no symptoms.

I am indebted to Prof. W. G. Barnard, then Director of the London County Council Histological Laboratory, for the excellent photomicrographs. He reported on the sections as follows:

"Purulent diverticulitis of caecum. The diverticulum is typical of the more common diverticula of colon. It is a hernial protrusion of mucosa and submucosa through the muscularis, and because of this is called a false diverticulum, to distinguish it from a true diverticulum, which would have the addition of the muscular coats in its wall. In Fig. 1 the abrupt termination of the caecal muscular coats on each side of the diverticulum is clearly shown, as are the mucosa and submucosa composing the wall of the diverticulum. At one side of the diverticulum the mucosa is missing, and here there is a purulent infiltration which has spread to the pericaecal fatty tissue (Fig. 2)."

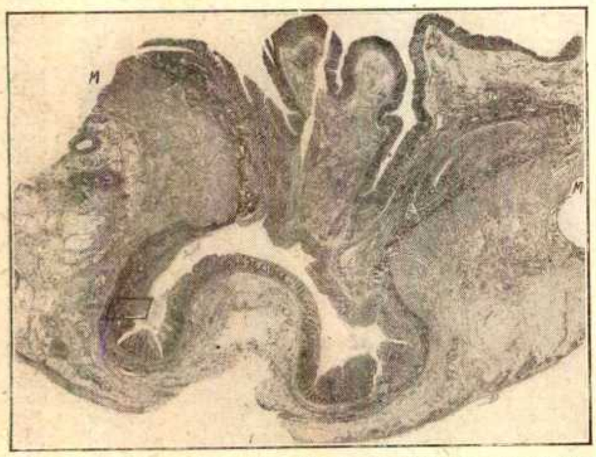

FIG. 1.—Section through solitary diverticulum of caecum. The abrupt termination of the caecal muscular coats (M) on each side of the diverticulum is clearly shown.

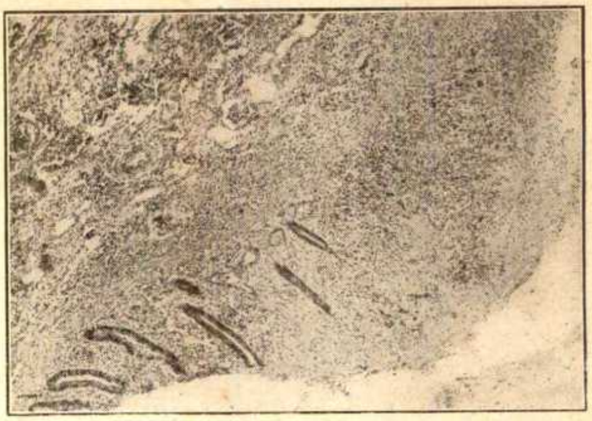

FIG. 2.—High magnification of the area outlined in ink in Fig. 1, showing purulent inflammation.

Summary

A case of purulent inflammation in a solitary diverticulum of the caecum is reported. The aetiology of the condition is discussed and local excision is recommended as the best treatment.

PENICILLIN AND FIBRINOLYSIS

BY

KENDAL DIXON, M.B., Ph.D.

Major, R.A.M.C.; Fellow of King's College, Cambridge

Staph. pyogenes can produce an enzyme fibrinolysin or fibrinase which may dissolve the clot produced by its own coagulase activity (Gonzenbach and Uemura, 1916; Gengou, 1933; Reimer, 1936). Some strains are more active in fibrinolysis than others. This fibrinolysis is well seen on inoculating 0.2-ml. quantities of human citrated plasma (diluted 1 : 4) in 2 in. by 3/8 in. test-tubes with a large loopful of a 24-hour broth culture of a strongly fibrinolytic strain of *Staph. pyogenes*. After 3 hours' incubation the contents of the tubes have solidified to a gel, but after further incubation for 3 to 6 hours the clot redissolves completely. These facts are illustrated in Table I, which compares the fibrinolytic activity of two strains—one strongly *fibrinolytic*, the other *afibrinolytic*.

TABLE I.—*Comparative Activity of Fibrinolytic and Afibrinolytic Strains of Staph. pyogenes*

	Clot Present After 3 hrs.	Clot Present After 6 hrs.	Clot Present After 9 hrs.	Colour to Neutral Red Initially	Colour to Neutral Red After 9 hrs.
0·2 ml. plasma 1 : 4 inoculated with 1 loopful of a 24-hr. broth culture of a coagulase-positive *fibrinolytic* strain of Staph. pyogenes	+ + + +	– –	– –	Yellow "	Pink "
0·2 ml. plasma 1 : 4 inoculated with 1 loopful of a 24-hr. broth culture of a coagulase-positive *afibrinolytic* strain of Staph. pyogenes	+ + + +	+ + + +	+ + + +	" "	" "

NOTES ON TABLE I.—(1) Double results refer to duplicate experiments. (2) 0.02 ml. of 0·04% neutral red added to each tube. (3) + + indicates coherent clot occupying major portion of contents of tube. + indicates some clot. – indicates absence of clot.

It will be seen from Table I that the first strain of *Staph. pyogenes* has caused the complete solution of the clot formed by its own coagulase activity within 6 hours of putting up the experiment. The second strain has failed to dissolve the clot even after 9 hours' incubation. Both strains, however, were equally effective in the production of acid. It has recently been suggested by Wilson Smith and Hale (1944), in a valuable study on the mechanism of coagulase activity, that fibrinolysis by *Staph. pyogenes* is associated with dissolution of the clot in the presence of acid formed by the growth of the organism. It is true that acid is formed simultaneously with the solution of fibrin, but fibrinolysis does not merely consist in the solution of fibrin at a low *p*H, since acid is formed just as readily by strains which cannot readily dissolve fibrin. Fibrinolysis and fermentation are independent phenomena.

Fibrinolysis is readily shown by suitable strains of *Staph. pyogenes* which produce both intense coagulation and rapid subsequent clot solution. Many such strains have been isolated from cases of pyodermia kindly sent to me by Major J. H. Twiston Davies, R.A.M.C. The only available subculture of the Oxford staphylococcus, however (possibly owing to loss of activity by repeated subculture), produced an inconstant and attenuated fibrin web under these conditions, and was therefore not suitable for the study of fibrinolysis.

Penicillin inhibits haemolysis by haemolytic streptococci (Wilson, 1943; Rammelkamp, 1942; Fleming, 1943, 1944). It appeared of interest to ascertain whether penicillin also interferes with fibrinolysis by *Staph. pyogenes*. Since this work was started an account of the inhibition of fibrinolysis by haemolytic streptococci has come from America (Neter and Will, 1944). That penicillin also inhibits fibrinolysis by *Staph. pyogenes* will be clear from the results which follow.

Varying quantities of penicillin dissolved in 0.05 ml. of distilled water are added to 0.05-ml. quantities of human citrated plasma in sterile 2 in. by 3/8 in. test-tubes; 0.10 ml. of saline is added to each tube to give a final volume of 0.20 ml. Then each tube is inoculated with one loopful (2 mm. diameter) of a 24-hour broth culture of a penicillin-sensitive coagulase-positive strain of *Staph. pyogenes,* known from previous experiments to be active in dissolving fibrin. After 3 hours' incubation a clot is seen to have formed in each tube, both in the presence and in the absence of penicillin. But after a further 9 hours' incubation (or even earlier) all the clot is dissolved in the control tubes without penicillin. With concentrations of 0.1 unit of penicillin per ml. and above, the clot remains unchanged, fibrinolysis having been completely inhibited. With less than 0.1 unit per ml., although fibrinolysis is sometimes delayed at the start, disintegration of the clot is generally complete after 9 or 12 hours' total incubation. The results of a typical experiment are recorded in Table II.

TABLE II.—*Action of Penicillin on Penicillin-sensitive Strains of Staph. pyogenes*

Final Concentration of Penicillin in Oxford Units per ml.	Presence or Absence of Clot After Varying Periods of Incubation Following Inoculation with Staph. pyogenes (Penicillin-sensitive and Fibrinase-positive)				Growth After 21 hrs.

0·025	++	−	−	−	+
	++	−	−	−	+
0·05	+	+	−	−	+
	++	−	−	−	+
0·10	++	++	++	++	−
	++	++	++	++	−
0·25	++	++	++	++	−
	++	++	++	++	−

NOTES ON TABLE II.—(1) Double results refer to duplicate experiments. (2) All tubes contained 0·10 ml. saline and 0·05 ml. human citrated plasma. Final volume made up with distilled water containing varying amounts of penicillin to 0·20 ml. (3) ++ indicates presence of large coherent clot occupying a large part of contents of tube. + indicates presence of some clot. − indicates absence of clot.

Penicillin inhibits fibrinolysis by penicillin-sensitive *Staph. pyogenes* readily also in the presence of serum. This action can be used for the detection and estimation of penicillin in serum. The serum sample for estimation is progressively diluted with penicillin-free serum obtained from the same patient before treatment. Human citrated plasma is added, and each tube is inoculated with fibrinolytic *Staph. pyogenes* as in the above experiments. The titre down to which fibrinolysis is inhibited is determined and compared with controls, using the same penicillin-free serum with added known quantities of penicillin. These control experiments determine the end-point of fibrinolysis with the particular serum employed. It is important to use penicillin-free serum obtained from the same patient before treatment, both as diluent for the serum sample to be tested and in the controls with known amounts of penicillin; otherwise errors due to the presence of antifibrinolytic agents (see Tillett and Garner, 1933; Stuart-Harris, 1935) may arise. This procedure also controls any effect due to decomposition of penicillin in presence of serum (see Bigger, 1944). Some sera are, however, so resistant to fibrinolysis that their penicillin content cannot be measured by this method. Fleming's (1944) recently described method is thus preferable.

Results employing this effect of penicillin on fibrinolysis have, however, found the penicillin concentration in the serum to be of the order of 3 units per ml. 15 to 30 minutes after intramuscular injection of 1,000,000 units, and to be 0.4 to 0.8 units per ml. after 1 hour.

In contrast to the action of penicillin on the fibrinolysis by penicillin-sensitive *Staph. pyogenes,* with *insensitive* strains no such action is observed. Table III demonstrates the failure of penicillin to inhibit fibrinolysis by an insensitive strain.

TABLE III.—*Action of Penicillin on Penicillin-insensitive Strains*

Final Concentration of Penicillin in Oxford Units per ml.	Presence or Absence of Clot After Various Periods of Incubation with Penicillin-insensitive Fibrinase-positive Staph. pyogenes		Growth After 21 hrs.
	3 hrs.	9 hrs.	
0·00	++	−	+
0·05	++	−	+
0·10	++	−	+
0·20	++	−	+
0·50	++	−	+
1·00	++	−	+

NOTES ON TABLE III.—(1) All tubes contained 0·10 ml. human plasma previously diluted with an equal volume of saline and 0·10 ml. water, containing varying quantities of penicillin, to give a final volume of 0·20 ml. (2) Symbols have same connotation as in Table I.

The results in Table III show that concentrations of penicillin which inhibit growth and fibrinolysis with *sensitive* strains of *Staph. pyogenes* fail to do so when *insensitive* strains are employed. The action of penicillin in inhibiting fibrinolysis is therefore connected with the inhibition of growth and metabolism, rather than with actual inhibition of the enzymic process of fibrin solution.

Under the conditions studied penicillin did not interfere with coagulase activity, presumably because sufficient preformed coagulase was present in the inoculum to cause rapid deposition of fibrin. The formation of acid, however, which accompanies growth and fibrinolysis is inhibited by penicillin with penicillin-sensitive strains. This is illustrated in Table IV.

TABLE IV

Final Concentration of Penicillin in Oxford Units per ml.	Presence or Absence of Clot After Varying Periods of Incubation with Fibrinolytic Strain of Staph. pyogenes		Colour of Contents of Tubes Before and After Incubation (0·02 ml. of 0·04% Neutral Red was Added to Each Tube)	
	3 hrs.	9 hrs.	Initially	9 hrs.
0·00	++	−	Yellow	Pink
0·025	++	−	,,	,,
0·05	++	−	,,	,,
0·10	++	−	,,	Orange
0·25	++	++	,,	Yellow
0·50	++	++	,,	,,

NOTES ON TABLE IV.—(1) All tubes contained 0·10 ml. human citrated plasma previously diluted with an equal volume of saline and 0·10 ml. water containing varying quantities of penicillin. To each was added 0·02 ml. of 0·04% neutral red. Final volume, 0·22 ml. (2) Symbols have same connotation as in Table I.

It is seen from the results shown in Table IV that the *p*H changes which normally accompany growth are abolished by penicillin at the same time as the interruption of fibrinolysis.

With a penicillin-insensitive strain, on the other hand, the production of acid is not susceptible to inhibition by penicillin. This is shown in Table V.

TABLE V

Final Concentration of Penicillin in Oxford Units per ml.	Presence or Absence of Clot After Varying Periods of Incubation with Penicillin-insensitive *Afibrinolytic* Strain of Staph. pyogenes		Colour of Contents of Tubes Before and After Incubation (0·02 ml. of 0·04% Neutral Red was Added to Each Tube)	
	3 hrs.	9 hrs.	Initially	9 hrs.
0·00	++	++	Yellow	Pink
0·025	++	++	"	"
0·05	++	++	"	"
0·10	++	++	"	"
0·25	++	++	"	"
0·50	++	++	"	"

NOTES ON TABLE V.—(1) Quantities of reagents employed were the same as n Table IV. (2) Symbols have same connotation as in Table IV.

It is seen from the above results (Table V) that even 0.5 unit of penicillin per ml. has not interfered with the production of acid by insensitive *Staph. pyogenes*, which is in marked contrast to the results in Table IV when a sensitive strain was employed. The results in Table V also demonstrate the separate nature of the phenomena of fibrinolysis and acid production. The strain used was *afibrinolytic*, and in spite of good acid production (at all penicillin concentrations used) solution of fibrin did not occur.

Fibrinolysis by *Str. pyogenes* (Group A) is also inhibited by penicillin (as was shown by Neter and Will, 1944). Using the technique described above, this action was found with one strain down to 0.025 unit of penicillin per ml., and with another to 0.0125 unit per ml. As *Str. pyogenes* does not form coagulase, 0.02 ml. of 1% calcium chloride was added to each tube to give the preliminary fibrin clot.

This inhibitory action of penicillin on fibrinolysis by both *Staph. pyogenes* and *Str. pyogenes* may be responsible for some of the therapeutic effects of penicillin, since prevention of the dissolution of fibrin barriers would counteract the spread of infection.

Summary

Penicillin inhibits fibrinolysis by penicillin-sensitive fibrinolytic strains of *Staph. pyogenes*.

The clot produced in human plasma by coagulase activity redissolves on further incubation, but fails to redissolve in the presence of penicillin at concentrations as low as those necessary to inhibit growth.

This effect is shown with penicillin-*sensitive* but not with penicillin-*insensitive* strains of *Staph. pyogenes*, and is presumably connected with the inhibition of growth.

I am very grateful to Major-Gen. L. T. Poole for his kind interest in this work, also to Major J. H. Twiston Davies, Lieut.-Col. C. H. Stuart-Harris, and Major S. T. Cowan for valuable advice. I wish to thank Sgt. J. R. McDonald and Sgt. J. Smith for their able assistance.

The *Soviet Medical Chronicle* for March, 1945, prepared by the Anglo-Soviet Medical Council in London from material supplied by the U.S.S.R. Society for Cultural Relations, Moscow, reports the reopening of the Pirogov Museum in the village of Sheremetka, not far from the city of Vinnitsa in the Ukraine. This museum is dedicated to Nikolai Pirogov, the famous surgeon (1810–81), known as the father of Russian medicine. During their occupation the Germans turned it into a stable and destroyed many valuable exhibits. When they retreated from the village the Germans planted mines both in the house in which Pirogov had lived and worked, and in his tomb. At the risk of their lives the villagers removed the mines and saved the museum. Later on the staff of the local hospital helped to repair the building, which is now open to visitors again.

Medical Memoranda

Identical Disease in Identical Twins

Kallmann and Reisner (1943), in an enlightening study recently reviewed in this *Journal* (1944, **2**, 504), confirmed the conclusions arrived at by various other authors that "hereditary factors play a decisive part in both the origin and the clinical course of tuberculous disease." An extensive literature—mostly German—on this subject is to be found in the original paper.

As a contribution to the pathology of twins the following cases may be of some interest.

The twins in question are 7-year-old daughters of a tuberculous mother under my treatment. These little girls, so far as I am able to judge, are identical—monozygotic—twins. In the course of routine contact examination of the children I learnt that they were complaining of cramp-like abdominal pains. The plain abdominal radiographs of the twins show calcified mesenteric glands, so alike in size, site, and configuration that one feels entitled to call them identical. As the two radiographs were taken on different days some allowance should be made for a slight difference in positioning, with slightly different projection of the glands in relation to the spine. There is no doubt that in both cases exactly the same group of glands is affected.

Diffuse Peritonitis from Gangrene of Hernial Sac

Gangrene of a hernial sac, though rare, is well known. It may or may not be associated with gangrene of the sac contents, the latter usually occurring in an elderly patient with a long-standing hernia. However, the following case, if not unique, appears to be of such rarity as to be worth recording.

A man aged 59 was admitted to the City General Hospital, Sheffield, on Nov. 15, 1944, for retention of urine. The relevant history was that six months previously he developed bilateral inguinal herniae, for which he was given a truss. This did not control either side adequately, and 10 days before admission the left hernia became irreducible, painful, and tender. This local tenderness was followed by colic pain, nausea, and later vomiting, also with absolute constipation for four days and retention of urine 12 hours before admission, for which he had been catheterized.

On examination his general condition was poor, he was dehydrated, and his tongue was red and dry. The abdomen was distended, tender all over, but intestinal sounds were present. In the left inguinal canal there was a tender swelling, which was irreducible, non-expansile on coughing, and covered by red oedematous skin. Seven oz. of urine was withdrawn by catheter. The provisional diagnosis was strangulated omental hernia with abscess formation and early peritonitis. Operation was immediately performed under local analgesia. Pus was found under the skin around and in the hernial sac, which was gangrenous, though the omentum, the only contents of the sac, was viable. The pus within the sac was aspirated; but on displacing the omentum pus welled out from within the abdomen. The sac was excised and the viable peritoneum at the internal ring closed. The skin was loosely sutured, with drainage to the peritoneum. He was given morphine, and an intravenous drip was inserted, but death occurred some 27 hours later.

Necropsy showed diffuse suppuration in the left inguinal canal and acute diffuse peritonitis, starting from the region of the left internal abdominal ring. No cause for the lesions was found, as the gut and omentum were viable and the gangrenous sac had been excised at operation.

I wish to thank Dr. Rennie, M.O.H., and Dr. Clark, medical superintendent, for permission to publish this case.

A Case of D.D.T. Poisoning in Man

Extensive studies on the toxicity to mammals of the new insecticide, 4,4'-dichlor-diphenyl-trichlorethane, commonly known as D.D.T., have shown that this substance is primarily a nerve poison, producing excitability, muscular tremors, clonic convulsions, and finally paralysis and death. It also causes a leucocytosis, anaemia, changes in blood calcium, and fatty degeneration in the liver and kidneys. It is absorbed readily through the skin, particularly when dissolved in kerosene (Cameron, 1943; Domenjoz, 1944; Draize *et al.*, 1944; Lillie and Smith, 1944; Neal *et al.*, 1944; Nelson *et al.*, 1944; Smith and Stohlman, 1944; Woodard *et al.*, 1944). In spite of a careful search among persons who have handled D.D.T. over long periods, no instance of poisoning in man has so far been reported. It seems desirable, therefore, to put on record the following case.

CASE HISTORY

The subject was a laboratory worker, about 30 years of age, in perfect health. Being unaware of the risk of absorption through the skin, leading to a general intoxication, and being anxious to discover whether D.D.T. was liable to cause any local irritation, he deliberately allowed small quantities of an acetone solution (acetone is one of the best solvents for D.D.T.) to evaporate on the back of the hand, the residual deposit being swabbed off with cotton-wool soaked in acetone. No erythema or any kind of skin irritation was observed. At least one further and more complete exposure was carried out, during which the subject's hands were in prolonged contact with the compound in acetone solution. In the course of these experiments an acetone solution containing about 25 g. of D.D.T. was added to an inert dust and the mixture kneaded with the hands for some minutes. During this operation the mixture completely covered the hands almost to the wrists. When the hands were taken from the mixture the solvent rapidly evaporated, leaving a dry deposit on the skin, which was removed as before by swabbing with acetone.

From one to ten days later a feeling of heaviness and aching developed in all the limbs, with weakness in the legs. There were also what the subject described as "spasms of extreme nervous tension." There was some improvement during a holiday taken at this time; but on returning to work the condition deteriorated, and some three weeks later the perpetual aching in the limbs confined the patient to bed. Sleep became almost impossible, the feeling of extreme nervous tension became more frequent, and a state of acute mental anxiety developed.

About six days after being confined to bed involuntary muscular tremors occurred over the whole body, and these were experienced on at least two subsequent occasions. After 10 to 14 days the patient got up, although the aching in the limbs was still severe. His recovery was very slow. He was away from work for 10 weeks in all, but even at the end of a year recovery was not quite complete.

During his illness it occurred neither to the patient nor to the neurologist and others whom he consulted that this might be a case of D.D.T. poisoning. Anxiety occasioned by the mysterious nature of his complaint was probably the cause of some of the symptoms (which are not here recorded); his condition immediately began to improve when he realized that his was almost certainly a case of poisoning by D.D.T.

The general consensus of opinion, based on experiments with animals and observations on man, is that D.D.T. used with discretion does not constitute a hazard to human health. The case here recorded is the exception which tests the rule. Symptoms closely resembling those seen in animals developed only after a deliberate exposure to D.D.T. far in excess of anything that would be likely to occur in practice.

Reviews

THE NATURE OF COURAGE

The Anatomy of Courage. By Lord Moran. (Pp. 216. 8s. 6d.). London: Constable and Co.

Lord Moran served as medical officer with one of our finest infantry battalions in the last war, and kept a diary in which he wrote of the minds and behaviour of men under stress of battle—studies which reveal his remarkable powers of observation and description. Extracts from the diary are interwoven in this book with present reflections enriched by the author's contact during this war with statesmen and officers of high rank in the fighting services—men who are interested as he is in the vital problem of morale. Wars are won, Lord Moran reminds us, by the courage and endurance of the few who are like rafts to which all the rest of humanity clings for support and for life. It is they who set the standard for victory. Fear is the enemy in himself with which a man must ever contend, and must vanquish if he is to play his part in the issue of success. This secret battle the author watched in the officers and men of his battalion, and in himself, through the vicissitudes of three years from the high-spirited days of 1914 to the last weary trench winter of 1917. He writes of the discovery of fear in men of all sorts, appearing in ways which are as many and various as their personalities, of fearlessness, of the ebb and flow of courage, and of the care and management of fear. His pages are alive with vivid intimate sketches of men seen at their critical moments of opportunity for success or failure in the venture which, as he says, is now not as of old the trade of the mercenary or the lot of the unimaginative, but the ordeal which every citizen must expect, whatever the stuff he is made of and whatever may be his attitude towards war. It is an ordeal which has borne hardly upon some of those brought up between the two wars to regard war as a senseless folly which solves nothing.

This book makes good reading, but critically regarded it lacks order and aim, and the reader who looks for deep and original thought may be disappointed. The distinction between war neurosis and concussion is dealt with in a way which might lead the uncritical to suppose that the blast effect of a shell may be responsible for the former—the hypothesis of shell shock abandoned in the last war and unsupported in this—and the assumption is made that a man may become an epileptic as the result of emotional strain. These are minor blemishes in a volume which is full of good stories and crisp thought, but are none the less unfortunate. The final chapter, on leadership, shows the author at his best and reveals his wide knowledge of military history. The book, one hopes, will be read by all medical and commanding officers of combatant units, for it cannot fail to excite thought and advance inquiry into the means of keeping the soldier's mind fit for his job—a task which is now widely recognized as the joint responsibility of commander and doctor.

A PRIMER OF SOCIAL MEDICINE

A Handbook of Social Medicine. By Fred Grundy, M.D., D.P.H. (Pp. 172; illustrated. 8s. 6d.) Luton: The Leagrave Press. 1945.

Dr. Grundy has written this book on social medicine to help midwives in their studies as hospital pupils, and in their practice. The matter it contains is an expansion of his own lectures to pupil midwives. As an aid to study and practice it ought to be useful not only to midwives but also to other nurses in the social health services.

The subjects dealt with cover many wide fields of knowledge and practice, but of course they are handled very briefly for the special needs of the readers. The sections deal in turn with the administrative structure of the socio-medical services, central and local; with the individuals concerned, women and children, in their environment; with the relevant problems of infection; with social biology and vital statistics; and provide a historical sketch of midwifery, an account of the Midwives Acts, and a useful extract from the Rushcliffe Committee report.

There can be no question that if the midwife is to be really competent and interested in her clinical practice she requires a great deal of the information abstracted and compiled by Dr. Grundy. A condensation of the vast miscellaneous knowledge which swells out the ordinary textbooks of public health into a small handbook suitable for the needs of midwives and other nurses is a difficult task. In places the result is somewhat rough, untidy, and scrappy; but the main purpose is achieved in giving the midwife, both as a student and as a practitioner, a manual of reference of essential information about the laws and regulations, the administrative framework, and the wider purposes that underlie the daily clinical routine of her work. The sections on maternal and infant diet are too short; and the linking of the work of the midwife and the health visitor also needs expansion. A good deal is said about the child welfare services, and this inclusion is well justified. Dr. Grundy is persuaded and enthusiastic about the great potential of service the midwife can render. He also stresses the value of the informal education given by the midwife in the intimate personal contacts of her work; and he has done well to emphasize the value and importance of this part of the work of the midwife as teacher as well as practitioner.

SULPHONAMIDES AND THE RETICULO-ENDOTHELIAL SYSTEM

The Reticulo-Endothelial System in Sulfonamide Activity. By Frank Thomas Maher, Ph.D. Illinois Monographs in the Medical Sciences Vol. V, Nos. 1 and 2. (Pp. 232. $2.50 paper bound; $3.00 cloth bound). Urbana: University of Illinois Press. 1944.

This is a monograph describing work carried out for a Ph.D. degree. The author has sought to demonstrate the part played by the reticulo-endothelial system in the defeat of bacterial infections treated by sulphonamides. He has used rabbits as his experimental animals, and he infected them with a strain of *Staphylococcus aureus*, which in sufficient dose was uniformly fatal in the absence of treatment. To determine the part played by the reticulo-endothelial system, thorotrast was injected intravenously, after which the liver, spleen, lungs, and kidneys were found to be impregnated with granules of thorium dioxide. In the dose used (3 c.cm. per kg.) thorotrast had no toxic effect. The injection of thorotrast was believed by the author to have depressed the reticulo-endothelial system for about 48 hours, because during this period the conjugation of sulphanilamide and of sulphathiazole to form the corresponding acetyl derivatives was depressed. Doses of the staphylococcal culture which were not lethal for all normal rabbits were lethal for a greater proportion of rabbits treated with thorotrast.

Sulphathiazole, given in suspension in olive oil by subcutaneous injection, protected rabbits against the staphylococcal infection, though this protection was not complete. Sulphathiazole, however, failed entirely to afford protection against the infection in rabbits treated with thorotrast during the period in which the reticulo-endothelial system was depressed. After recovery—e.g., 4 days after thorotrast administration—sulphathiazole once more assisted in overcoming the infection.

The author recognizes that the staphylococcus was not the best organism to use for this work, but he failed to obtain a culture of *Streptococcus haemolyticus* which was uniformly virulent. Perhaps the most interesting part of the monograph is that which suggests that the reticulo-endothelial system is responsible for the chemical reaction of conjugating sulphonamides with acetic acid.

COLORIMETRIC METHODS OF ANALYSIS

Colorimetric Analysis. By Noel L. Allport, F.R.I.C., Research Chemist, British Drug Houses, Ltd. (Pp. 452. 32s.) London: Chapman and Hall. 1945.

To those who have occasion to perform colorimetric determinations a vast array of methods is available in the technical literature, and it is often difficult to choose the most suitable one. In the book under review the author has successfully presented a detailed account of the more useful colorimetric methods of analysis in a volume of moderate size and cost; only those which have proved satisfactory in his own experience are included.

The book is divided into five sections. Sections I and II deal with the determination of metallic and acidic radicals; Section III with substances of medical or biochemical significance; Section IV with alkaloids, hormones, and vitamins; and Section V with miscellaneous substances. In Sections I and II the sections on the determinations of poisonous metals in food and biological material are of interest to the toxicologist; a bibliography of references to the original papers is given at the end of each monograph. Section III will prove instructive to the medical student, and of value to the clinical pathologist who may wish to perform, at possibly infrequent intervals, determinations of therapeutic substances in biological materials without an extensive search through original literature, or preliminary trials on standard materials to test the suitability of a given method. We think the discussion in each section on the limitations of the various methods should prove useful as an indication of possible sources of error when modifications are introduced to meet the requirements of a particular sample. In Section IV recent improvements on the well-known Stas-Otto method for the isolation of alkaloids from viscera are discussed as well as the colorimetric determination of the alkaloids themselves. Finally, Section V describes a number of disconnected determinations; one, for example, of considerable importance in relation to public health, being the determination of free chlorine in drinking-water.

The author and publishers are to be congratulated on producing a book which is well bound and commendably free from the usual minor typographical errors almost inseparable from a new publication.

Notes on Books

It is nearly forty years since the late Dr. J. D. Comrie prepared for Messrs. Adam and Charles Black the medical dictionary which bears their name. Now for its eighteenth edition Dr. HUGH CLEGG has undertaken the heavy task of revision so that *Black's Medical Dictionary* (Adam and Charles Black; 18s.) can continue to take its high place among books of this type. Looking first for recent advances the reviewer finds these adequately and succinctly covered; indeed, on such matters as the Rh factor the brief type of summary possible is excellently done. Two pages of "special suggestions" at the beginning of the volume give a valuable guide for the use of its contents, especially in an emergency. As a wartime production the whole book is excellently printed and firmly bound, all for a most modest price for just short of a thousand pages. Dr. Clegg was a fortunate choice for a successor to Dr. Comrie, and the wide public—medical and lay—who use this dictionary must be grateful for his competent revision.

The 1944 *Year Book of Pediatrics* (H. K. Lewis and Co.; 18s.) once again brings an excellent choice of abstracts, skilfully edited, with occasional editorial comments, by Prof. I. A. Abt and Prof. A. F. Abt. About 400 names of authors are listed to account for over the same number of pages of text. A special review of the literature on the Rh factor has been contributed by Dr. I. Davidsohn, and in this, as elsewhere in the book, there are numerous references to British literature. The work of the British Paediatric Association in its survey of rickets (in 1943) and in its joint statement with the Cardiac Society on the care of rheumatic children receives welcome recognition by long annotations. The editors sadly record after an abstract of an article on intestinal obstruction in childhood that it is "probably the last published article of the lamented and much-loved Joseph Brennemann." Plenty of space is given to the many uses of the sulphonamides in childhood; penicillin, on the other hand, has barely crept in this year, though undoubtedly it will be prominent in the next volume. Altogether the standard of this valuable reference book is being well maintained despite present-day difficulties.

The appearance of a sixth edition of the *Clinical Atlas of Blood Diseases* (J. and A. Churchill; 16s.) by A. PINEY and S. WYARD testifies to the continued popularity of this little book. It is essentially an illustrated catalogue of blood pictures, and in these days of overcrowded curricula it provides as much special knowledge of haematology as the undergraduate needs. It could probably be still further simplified. There are references to some mythical diseases such as Gamma's disease and David's disease, and the arrangement of the material is capricious, as in the intercalation of myelosclerosis and Albers-Schönberg disease between alimentary anaemia and chlorosis.

The Department of Health for Palestine has issued *A Nutritional Economic Survey of Wartime Palestine 1942–3*, by Dr. W. J. VICKERS, senior medical officer. This document runs to 116 printed foolscap pages, a map, and 26 graphs. Col. Sir George Heron, Director of Medical Services, Government of Palestine, contributes a foreword. The price of the report, which has been printed at Jerusalem by the Government printers, is 250 mils. The copy that has reached here may be consulted in the Library of the British Medical Association.

IMPRESSIONS OF PARIS

BY

Prof. L. P. GARROD, M.D., F.R.C.P.

Such is the claustrophobia induced by over five years' confinement in England that the opportunity of visiting almost any other country would be welcome: of opportunities for escape an invitation to lecture in Paris is among the more delectable. So exhilarating is the atmosphere of this city that the formidable prospect of speaking in French in the Amphithéâtre Richelieu at the Sorbonne can be faced with almost a light heart, and even the discovery that one has been widely advertised as giving three lectures instead of the two carefully prepared before departure causes only momentary misgivings. A quiet room at the Cité Universitaire—where one block has been retained in the Maison Internationale for the reception of the more academically inclined foreign visitors—and some hard work with the blue pencil by good friends in whose language the stuff is written, and the gap is filled. The subject of all three is progress in chemotherapy since 1939, with a good deal of emphasis on penicillin; and if they were well received three qualities in the audience are largely accountable—their thirst for knowledge of what has been happening during their four years of isolation, their admiration for everything British, and their intense curiosity about penicillin. The generous loan from Oxford of the now famous penicillin films added more than a touch of colour to the lectures themselves.

So far as penicillin is concerned France is where we were early in 1943—with a difference. Supplies are on the same very small scale, and are allotted exclusively to three hospitals in Paris and a few in the provinces. The main difference is due to the fact that all France seems almost incurably black-market-minded. There are actually two black markets in penicillin—the true and the false. The stock-in-trade of the former is the genuine article stolen from American Army stores; of the latter, in one instance of which I heard, the purchaser having paid 50,000 francs for a tube labelled penicillin, it was a mixture of sodium carbonate and talc. Nothing can excuse the vendor of the spurious article, but let those who are tempted to blame the buyer, whether of this or of any other black-market commodity—not only food of almost all kinds, but petrol, paper, and indeed almost what you will—reflect that throughout the German occupation our Radio steadily encouraged this subversive activity. Antisocial conduct of this and other kinds was a duty to France during the German administration: is it surprising that these methods persist even though their justification has been removed?

A substantial share of the penicillin in Paris goes to the Hôpital Claude Bernard, where Lemierre kindly showed me cases under treatment with it, and much else besides. This magnificent hospital is uncomfortably close to the Porte de la Chapelle railway yards, which were the target of a heavy British raid on a moonlight night in April last year. The French are enthusiastic about not only the devastating effects but the accuracy of our bombing, and the cost of this attack —a single bomb which destroyed one block, damaged two others, and killed forty patients—seems to have been accepted willingly. This immense hospital is a paradise for those whose concern is microbic infection. It receives almost all cases of adult infectious disease in Paris, and besides the infectious fevers admits many patients suffering from acute infections which are non-communicable in this sense. I saw several cases of staphylococcal septicaemia, two of severe puerperal fever, two of influenzal pneumonia, one of tetanus, and two first-class undiagnosed mysteries. Lemierre's own service comprises 400 beds, and his experience of some of these conditions must be unrivalled: he has a series of photographs of carbuncle of the face, with and without cavernous sinus thrombosis, and can assess the prognosis in this condition with such confidence as to withhold penicillin treatment when he considers that the patient will recover without it—as indeed he had in one patient whom I saw. Where else, too, will you find it recognized that septicaemia due to *Bacillus funduliformis* presents a characteristic clinical picture? Here is obviously a first-class centre not only for using penicillin to save life, but for exploring some of the more remote and less familiar fields in which it may prove useful.

The Pasteur Hospital exercises similar functions on a smaller scale, and here René Martin has been doing the same type of work. He has, I think, added definitely to our knowledge of penicillin therapy in one direction at least. It is now a truism that the scarcity of penicillin in England has forced us to exploit the possibilities of local treatment to great advantage in efficiency as well as economy. Martin has been even more tightly confined in the same position, and when he could afford only a small quantity for treating a carbuncle, infiltrated the whole area by multiple injections—as for local analgesia—with a solution of penicillin containing 2% novocain. This was so successful that it has become the method of choice. The third Paris centre is the Hôpital pour les Enfants Malades, where Debré has taken full advantage of the much lower scale of dosage required in children and employed penicillin freely, in the treatment particularly of meningitis and pneumonia.

The background of these achievements is a state of affairs in which hospital administration must be a very anxious task indeed. There appears to be no shortage of domestic labour, even in the private houses of those who can afford it, but almost every commodity presents difficulties. Diet is doubtless the worst of these preoccupations: bread and vegetables are the only items of which the supply is at all dependable. It is almost impossible to replace any linen, and I did not discover how either linen or the patients themselves are washed. At all events there is a grave dearth of soap, and numerous advertisements of *eau de javelle* for laundry purposes are evidently a clue to the first of these riddles. At the end of a whole morning in hospital, when I expressed a desire to wash my hands (preferring this to the ritual immersion of the finger-tips in a bowl of antiseptic lotion) it was necessary for a sister to go in search of a key, by means of which she eventually produced from a cupboard a cube which seemed to consist mostly of abrasive material, although I am prepared to believe that the base which held it together had more or less the properties of soap. Of these shortages, that of food is of course the most serious, and one would like to be able to say what its effect has been on the health of the city population as a whole. No casual observer can possibly answer this question. Some effect there must have been, particularly on resistance to infection, and it is somewhat alarming to read that an influenza epidemic has begun in Paris complicated by a bronchopneumonia strongly reminiscent of 1918. Comparison between the circumstances of that year and the present has been made in the daily press. There is one feature of Paris life highly conducive to the spread of aerial infection—the appalling crush in the Métro, still the only form of public transport. It is exceptional to get a seat even at the slackest time; at busy hours the trains are crammed to the point of suffocation, and the last to enter have devised a special technique for compressing their neighbours and enabling the doors to close—it consists of advancing backwards, using the buttocks as a battering-ram. Possibly the garlic and perfume disinfect the atmosphere and so save what would otherwise be a dangerous situation.

France faces a far more serious situation when her 2,000,000 prisoners return, for 500,000 of them are believed to have phthisis. How to segregate this enormous number of men who will otherwise be a danger to the whole community is one of the biggest problems with which the country has to deal.

Masks in wards and the "no-touch technique" are evidently unheard of: this was the most obvious indication that the advances of the past five years have still to be learned in France. The foreign journals for that time are all missing, and it is difficult to see how the gap can be filled, either in the libraries or in the minds of those who use them. It may prove, too, that we have things to learn from what has been done in France: microbiology there has certainly not stood still, and of what may have happened in other fields I am no judge. The School of Medicine is crowded with students, following the liberation and owing to delayed call-up for military service, now of course four years in arrears. I had occasion several times to visit Gastinel, the professor of bacteriology, and to reach his sanctum had to pass through a large teaching laboratory which seemed always, even on a Saturday afternoon, to be full of students. It appears that each class in the course they were attending has to be held ten times to accommodate the present numbers. I can imagine no more soul-destroying drudgery for the teachers than classes multiplied to this extent, and our more parochial system in London of many separate medical schools, each a complete unit, has much, if not quite everything, to commend it. The complete pre-eminence of Paris as a medical school has no counterpart in this country. It is arguable that the magnificence of Paris as a city, and the concentration there of so much of the leading intellectual life of the country, are actually detrimental to France as a whole.

At the Institut Pasteur Tréfouel and his staff have made plans not only for the supervision of penicillin production in France but for exploring the still unsolved mysteries connected with its nature and action. Anyone familiar with their contributions to the study of other forms of chemotherapy will understand that much may be expected of this accession to the strength of those engaged in this research. The Institut came unscathed through the occupation, in spite of having been a depot for medical stores parachuted by ourselves into France. The only casualty of whom I have heard has a melancholy and historic interest. Joseph Meister, the Alsatian boy who was the first patient to receive prophylactic treatment for rabies from Pasteur, was still employed as gate-keeper at the Institut at the outbreak of this war: he committed suicide when the Germans entered Paris in 1940.

Whole-time salaries are now quite unrelated to the cost of living, which has reached astronomic figures for those who live in anything approaching normal style, and thus depend largely on the black market to fill their larders. Loans and lotteries are aimed at reducing the note circulation, but more powerful forces seem to be at work to depreciate the franc; and an advance of 40% in Métro fares while I was there seemed a public admission that the tendency is still in the wrong direction. The problems of currency, transport, food distribution, and reconstruction are formidable indeed, and French admiration for ourselves and the stability we have maintained in some of these matters knows no bounds. On our own part there seem to be two attitudes to France—one sympathetic, and the other not. To those of the latter persuasion I would recommend reflection on what is meant by four years of the Gestapo. To hear of executions and atrocities from the friends or neighbours of the victims is a very different thing from reading of them in the newspapers, and one evidently needs to be in an occupied country to know what a Nazi is. The people who would have us believe that these stories are exaggerated or even fabricated, and take in general the view that the sufferings of the French nation, both past and present, are less than they have been described, may be guilty of grave injustice, and are certainly doing disservice to the relations between our two countries.

CONTROL OF VETERINARY PRACTICE

The report to the Minister of Agriculture and the Secretary of State for Scotland of the Committee on Veterinary Practice by Unregistered Persons is published for the Ministry and Department as a White Paper (Cmd. 6611, H.M. Stationery Office; 3d.). The committee was set up in July, 1944, to inquire into the extent and effect of veterinary practice in Great Britain by persons who are not registered veterinary surgeons, and to make recommendations as to any measures for limiting or regulating such practice. After surveying the field the report sets out conclusions and recommendations.

The committee's main recommendation is that the practice of veterinary surgery by unregistered persons should be prohibited under penalty, but that this prohibition should not apply to the treatment of an animal by its owner, the rendering of first aid to an animal in an emergency, the destruction of an animal by painless methods, or the performance of castration and certain minor operations. It further recommends that unregistered persons who for any seven of the last ten years have been engaged as their principal means of livelihood in diagnosing and giving medical or surgical treatment to animals should be entitled to registration by the Royal College of Veterinary Surgeons in a register of "Existing Practitioners." Such persons, who must be of good character and not less than 28 years old, should be subject to disciplinary jurisdiction by the R.C.V.S., should have the same facilities as registered veterinary surgeons for obtaining necessary drugs, and should be allowed to use the title "registered animal practitioner." Another recommendation would empower the Minister and the Secretary of State to control the advertisement and sale of veterinary medicines. Provision should also be made for a ministerial declaration by Order that specified duties performed by unregistered persons under the direction of a veterinary surgeon are not subject to the prohibition of veterinary practice by unregistered persons.

COLONIAL MEDICAL RESEARCH COMMITTEE

The Colonial Office announces that the Secretary of State for the Colonies and the Medical Research Council have jointly set up a Colonial Medical Research Committee to advise them on medical research for the benefit of colonial territories.

The chairman is Sir Edward Mellanby, M.D., F.R.S., secretary of the Medical Research Council, and the other members are: Lieut.-Col. J. S. K. Boyd, R.A.M.C.; Prof. P. A. Buxton, F.R.S., London School of Hygiene and Tropical Medicine; Dr. A. N. Drury, F.R.S., Director of the Lister Institute of Preventive Medicine; Brig. N. Hamilton Fairley, M.D., F.R.S.; Dr. W. H. Kauntze, Chief Medical Adviser to the Secretary of State for the Colonies; Prof. B. G. Maegraith, Liverpool School of Tropical Medicine; Dr. B. S. Platt, Director of the Human Nutrition Research Unit, M.R.C.; and Major-Gen. Sir John Taylor, M.D.

The secretary of the committee is Dr. Frank Hawking, of the National Institute for Medical Research, M.R.C.

Nova et Vetera

E. B. BANCROFT: A VERSATILE PHYSICIAN

Sir Arthur MacNalty has done well to shed light (in a reprint from the *Proceedings of the Royal Society of Medicine,* Nov., 1944) on the life and achievements of Dr. Edward Bartholomew Bancroft, who lived in the eighteenth century while the profession of medicine was still largely empirical. He was a many-sided man—physician, eminent scientist, philosopher, politician, novelist, technical expert in dyes, and philanthropist. Born in Massachusetts in 1744, of good American yeoman stock, Bancroft was apprenticed to a trade, but ran away to sea and made several voyages.

He had evidently acquired some medical training aboard ship, possibly as surgeon's mate, for we next hear of him as medical attendant on a West Indies plantation and later in a like capacity in Dutch Guiana, where he studied the flora and fauna and gained a reputation as a botanist and zoologist, after the publication of his first book *The Natural History of Guyana* (1769), in which he wrote of tropical plants and their dye-producing properties. He also described various diseases: leprosy, yaws, which he treated by salivation with mercury; malaria, which he treated with bark; yellow fever; and the bites of venomous snakes. Bancroft came to England in 1765 and studied medicine, obtaining the degree of M.B., and later proceeded M.D. at Aberdeen University. On account of his scientific attainments he was soon recognized as a leading London physician and found time to make further researches into the production of colours and vegetable dyes, which gained him unanimous election as a Fellow of the Royal Society.

He was a contemporary of another famous physician, Dr. John Coakley Lettsom, whom he helped to found the Medical Society of London (1773). He was able among all his activities to write a number of treatises and novels, but his most important and successful work was *The Philosophy of Permanent Colours,* in which he displayed a profound knowledge for those days of chemistry and botany. This book was a valuable introduction to the chemical industries of to-day, and it became the standard British and American authority on the subject of dyes. During the American War of Independence (1780–3) Bancroft (then a British subject) rendered good service to the British cause. He supplied all the particulars of the French fleets and armies to the Government. He lived in Downing Street, Westminster, which was then a doctors' street. Tobias Smollett set up in practice there in 1744.

Sir Arthur MacNalty regards Bancroft as one of the most complex personalities in medical history. He was a genius endowed with great natural gifts and, coming to this country as an unknown person, early achieved a distinguished position as a scientific physician and chemist. His fatal gift of versatility proved a snare for his posthumous reputation. He died in 1821 aged 77.

S. L. Zimmerman and R. Barnett (*Ann. intern. Med.,* 1944, **21,** 1045) record a case of sickle-cell anaemia in a man aged 30 in whom the haemolytic crisis simulated a coronary occlusion clinically and to a lesser degree cardiographically.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY APRIL 14 1945

CIVILIAN MASS RADIOGRAPHY

Mass miniature radiography was introduced into the Royal Navy in 1939, and by 1941 Dudley[1] was able to report the results of 18,000 examinations. This and many similar publications from all over the world showed clearly the value of the new technique and the problems it raised. After such publicity the idea caught the public fancy and was approved by the Ministry of Health, but it was not until 1942 that a few official miniature radiography sets were produced for civilian use. The first of these went to the Medical Research Council, which has now published a report[2] on the first 23,000 examinations made with this instrument. About half of the report deals with the technique and organization of a miniature radiographic survey; this section is excellent and will undoubtedly become a standard work of reference on the subject. The account of the handling of apparatus, processing of films, and positioning of the patient is particularly good. The recommendations on the disposal of abnormal cases will, however, hardly meet with such general approval. It appears that in doubtful cases the medical directors of the unit must often decide from one interview and radiograph not only whether the subject has pulmonary tuberculosis but also whether the disease is active. Anyone who has had experience in a chest clinic will realize the absurdity of this suggestion; yet it is one which has often been made in the past, and even the official publications have implied that it should be the duty of the mass radiography unit to distinguish, in certain cases, between active and inactive pulmonary tuberculosis. In view of the overwhelming evidence that the majority of early tuberculous lesions in the lungs are symptomless, it is clearly most dangerous to decide on such slender evidence whether a newly discovered tuberculous lung lesion requires special action or not. The only safe course is to keep all patients with such lesions under close observation. The present official constitution of a mass radiography unit places a clinician in charge but does not give him control of the observation and investigation of suspects. Such an arrangement encourages the clinician to commit himself to a diagnosis, and even prognosis, on the strength of one interview and an *x*-ray film of the chest. Certain of the suggestions made in this report concerning the treatment of newly detected cases at a chest clinic invite similar criticism. It is stated, for instance, that in some cases a single re-check after 6 months may be all that is necessary to establish that a lesion is healed. But this makes no allowance for the rapidity with which some of these apparently healed lesions deteriorate. Even more revealing is the statement that "the present shortage of institutional beds makes it specially desirable to reduce as far as possible the number of cases referred for assessment." It was obvious 5 years ago that the introduction of mass radiography would bring to light a large number of cases requiring hospital observation for diagnosis, and it is disquieting that the shortage of suitable beds is, if anything, more acute now than it was then—in spite of full State control of the medical and nursing services.

The Medical Research Council's report concludes with statistical data on the incidence of tuberculosis and other pulmonary lesions in the persons examined. These figures are similar to those obtained in other mass miniature radiographic surveys. Although such statistics are interesting they throw no light upon the most important problem of all—the fate of the symptomless tuberculous lesion. An increasing number of such lesions are being discovered by modern diagnostic methods, and until the question is answered we shall be no nearer to the solution of the greater problem of the treatment of early pulmonary tuberculosis. If mass miniature radiography is to answer this question it must be used scientifically, as a diagnostic instrument, by the clinicians who are going to direct the observation, diagnosis, and treatment of the patients, and who will continue to observe them for months and even years until the research is complete. But, at present, mass radiography sets have been distributed to various local authorities, and each has become the centre of an independent unit. There is no general agreement about the procedure for the disposal of suspected cases: some advocate that the patients should be sent to their private doctors; others, that they should go direct to chest clinics, and so forth. In these circumstances an efficient survey of the fate of the patients will be extremely difficult if not impossible, and will inevitably lack the element of personal observation which is so important in research. Science does not lend itself to bureaucratic methods, and a clinical inquiry cannot be reduced to a matter of filling in forms.

In the Services the position seems more hopeful, and they have the undeniable advantage of dealing with a disciplined population. Trail and others,[3] in a recent survey of 250,000 miniature radiographic examinations in the Royal Air Force, state that an attempt was made to keep tuberculous suspects under observation, at least for 2 to 3 months. The results prove the value of this course, for 13% of the male and 15% of the female suspects developed active disease. But a short-term policy of this kind is not enough, and Trail and his colleagues are forced to admit that they have not information of the after-histories of all persons examined. By far the most ambitious attempt has been made by the Senior Service, which was also the first to adopt mass radiography. In 1939 units were installed at the three principal naval depots; all persons passing through the depots were examined, and every man in the Navy passes through one or other of them once in 3 years, when his ship pays off. Arrangements were made for the observation of suspects under the same medical control. All doubtful cases were admitted to hospital, where full clinical investigation enabled a preliminary assessment to be made in about 10 days. Those who had lesions of uncertain stability were given selected shore service, where they could be kept under supervision; they had adequate rations, suitable employment, and abundant rest and leave.' Medically they were seen as out-patients and admitted to hospital for repetition of investigations at intervals of 2 to 3 months. Brooks,[4] in a preliminary survey of this research in 1944, recorded that over half a million men and women in the Navy had been examined by miniature radiography: 2,911 sailors had minimal lesions in the lungs, and about 1 in 6 of these proved to be active; in a further 1,826, or 63%, the stability of the lesions was uncertain, and these were observed as described. The thoroughness of this investigation is shown by the fact that some of these cases had been observed for 2 years at the time of reporting: 191, or about 9.5%, of these suspects developed active tuberculosis while they were being watched; the majority of them relapsed during the first year. Thus it is clear that the future of over half the patients with minimal tuberculous lesions in the lung cannot be predicted after one examination, or even after a period of observation in hospital. At least one in ten will subsequently develop active tuberculosis, and if this is to be treated promptly the patient must be kept under the closest surveillance. The far-sighted research in the Royal Navy is doing a great service by providing vital information on the fate of early tuberculous lesions; it also ensures prompt treatment for naval personnel who develop active disease, and it has enabled many men to be retained in the Service who might otherwise have become tuberculous pensioners on the strength of an x-ray examination alone. With this model before us it is regrettable that we civilians should still have to ask the question: Is mass miniature radiography merely to be regarded as an interesting toy, with a useful propaganda value, or is it to be used as an instrument of scientific research?

IRIDOCYCLITIS

Iridocyclitis is one of the more common inflammations of the eye and is responsible for much visual impairment and a fair amount of blindness. The causes are many, but there is little clear knowledge of the relative significance of each. A time-honoured classification includes syphilis, gonorrhoea, tuberculosis, and rheumatism, but of late such factors as sarcoidosis, brucellosis, and various clinical syndromes have claimed attention. Of the syndromes, that named after Behçet is perhaps the most clear-cut. Recurrent hypopyon has been known to ophthalmologists for many years, but it was Behçet—a dermatologist—who pointed out the association of this form of iridocyclitis with recurrent aphthous ulcers of the buccal mucosa and herpetiform or aphthous lesions of the genitalia. The least constant in this triad are the eye symptoms, which, indeed, may range from recurrent conjunctivitis, corneal ulceration, and iritis to hypopyon uveitis; occasionally optic atrophy has also been observed. A variant in the skin condition is pointed out by Foss,[5] one of whose cases showed pyodermia and erythema nodosum. That the condition may be allergic is suggested by the fact that in his patient an attack was precipitated by staphylococcal vaccine. Recurrent hypopyon appears to be more common in men.

Iridocyclitis may be of little ultimate significance to the patient, or it may cause blindness. Essen-Möller[6] found that 42% of his 240 cases of chronic iridocyclitis recovered completely, and 32% went on to total or subtotal blindness. His careful analysis of the aetiological factors in his cases showed tuberculosis to be present to a significant extent in chronic iridocyclitis, as also in sclero-keratitis, but not in acute iridocyclitis and choroiditis. Characteristic of these difficulties in assessment is the concept of "pseudo-tuberculosis" applied to such conditions as sarcoidosis and uveo-parotid fever, which account for a certain proportion of cases of iridocyclitis. The readiness with which clinicians will ascribe a nondescript reaction to tuberculosis varies in different countries. On the Continent tuberculosis is favoured as a cause of iridocyclitis; in this country, "rheumatism." But in acute rheumatic fever iridocyclitis is a curiosity, and chronic rheumatism includes many ill-defined conditions. It was tempting to blame focal sepsis when the fashion ran high. In drawing attention to iridocyclitis in six cases of Still's disease observed at the ophthalmic department of the Finsen Institute in Copenhagen, Blegvad[7] stresses the fact that both conditions are rare in children. He therefore regards the concurrence of the two not as a coincidence but as a special form of Still's disease. Still himself never mentioned iridocyclitis in his cases. Blegvad found 20 similar instances out of a series of 896 children with polyarthritis observed in the State and communal hospitals of Denmark during 1929–39. Franceschetti and Brocher[8] state that this type of iridocyclitis is characterized by the formation of a band-shaped opacity in the cornea. They classify rheumatic affections in relation to iridocyclitis under the two main headings of (1) infective rheumatism, and (2) non-infective rheumatism. They divide the acute forms of infective rheumatism into those which are free of ocular complications, and those in which there are rheumatoid reactions—for example, in gonorrhoea, erysipelas, dysentery, smallpox, where indeed iridocyclitis is not rheumatic but part of the systemic infection. In the chronic forms iridocyclitis is common in what they describe as primary chronic polyarthritis, and in spondylarthritis; it is present in some cases of Still's disease, but has not been observed in Felty's syndrome—Still's disease in adults with leucopenia and occasional yellow-brown pigmentation of the unexposed skin. As the chronic, non-infectious forms of rheumatism are so common, it is difficult to decide whether the eye changes seen in the sufferers are no more than a coincidence.

It appears, then, that only three rheumatic affections have to be considered in iridocyclitis: primary chronic polyarthritis, mainly in women; spondylarthritis ankylopoietica, mainly in men; and Still's disease. A link between rheumatism and iridocyclitis is suggested by such conditions as Sjögren's syndrome and Reiter's syndrome, both characterized by polyarthritis and ocular lesions but not by iridocyclitis. In Sjögren's syndrome the eye lesion is a kerato-conjunctivitis sicca, and in Reiter's syndrome there is a purulent conjunctivitis.

[5] *Acta ophthal.*, 1941, 19, 293.

[6] *Acta ophthal.*, 1942, 20, 97, 121.

[7] Ibid., 1941, 19, 219.

[8] *Schweiz. med. Wschr.*, 1944, 74, 299.

While there is a growing awareness that any one of a large number of general disturbances may be responsible for iridocyclitis, and that there is still much to be done in establishing possible causal factors, the fundamental difficulty in the understanding of iridocyclitis arises from our ignorance of the nature of intra-ocular inflammation. Few instances of such inflammation are bacterial in origin, and the understanding of the mass of inflammatory disease of the inner eye is likely to elude us until there is a clearer appreciation of the character of non-bacterial inflammation.

A NEW THEORY OF DIGITALIS ACTION

The action of digitalis on the heart seems fated to be a subject on which investigators will always disagree, even in this country, where Withering first observed it. Mackenzie demonstrated its value in auricular fibrillation, and Lewis's analysis of the effect of digitalis in that condition led to the view, in this country and in America, that its chief use was in treating disorders of auricular rhythm by preventing them from disturbing the ventricle. Probably most British clinicians retain this view to-day. In America digitalis is held to be valuable for congestive failure where the rhythm is that of the sinus and the failure is due to disease of the heart muscle. This view was advocated on the Continent by Fraenkel,[1] who gained a reputation by giving strophanthin intravenously to relieve cardiac oedema in patients with normal rhythm. He used to say: "They come to me and tell me the treatment is wonderful: they feel so much lighter."

Recently McMichael and Sharpey-Schafer[2] have published some observations on the effect of intravenous injection of digoxin in man in which they have recorded the changes produced in the pressure in the right auricle together with those in the cardiac output. Adopting the method of Cournand and Ranges,[3] they insert a catheter into a vein in the left forearm; the catheter is pushed further and further into the vein until it is observed by *x*-ray illumination to come to lie at the entrance to the right auricle. Through a catheter in this position a sample of mixed venous blood can be withdrawn; by determining its oxygen content per c.cm. and subtracting this from the oxygen content of arterial blood the arteriovenous oxygen difference for the body as a whole is determined, and when this figure is divided into the oxygen intake per minute a figure for the cardiac output is obtained. McMichael and Sharpey-Schafer have now used this catheter to measure right auricular pressure.

When digoxin was injected the one constant effect they observed was a fall in the right auricular pressure. Out of 25 instances in which this fall occurred there was a rise in cardiac output in only 15. The ordinary explanation of a fall in right auricular pressure would be that the primary effect of digoxin was to stimulate the heart muscle, leading to a rise in cardiac output, and that the fall in right auricular pressure was secondary to this. But since in 7 observations the cardiac output fell and in 3 there was no change, McMichael and Sharpey-Schafer conclude that the effect of digoxin on right auricular pressure was primary and not a consequence of raised cardiac output. In support of this view they give evidence of a different kind. In 4 patients suffering from congestive failure they applied pneumatic cuffs to the thighs and so obtained a mechanical lowering of venous pressure. They found not only that this caused a rise in cardiac output but that in every instance it caused the same rise in cardiac output in relation to a given reduction of right auricular pressure as did digoxin. Thus they come to put forward a new view of the action of digitalis—that it is not on the heart at all but on some extracardiac mechanism which reduces venous pressure. They apply this explanation not only to simple congestive failure but also to failure in auricular fibrillation, where the beneficial effect of digitalis was ascribed by Mackenzie and by Lewis to the control of the heart rate; for McMichael and Sharpey-Schafer found that the effect of digoxin in causing a fall of venous pressure was similar in degree whether the failure was present when the rhythm was normal or was due to auricular fibrillation. A new theory of this kind is most stimulating.

SICKNESS AMONG WOMEN IN INDUSTRY

In Report No. 86 of the Industrial Health Research Board Dr. S. Wyatt[1] and his five assistants describe the results of an investigation into the sickness absence of munition workers. The 20,000 women concerned were employed at five factories where small-arms ammunition, fuses, shell cases, guns, and other equipment were manufactured, and the period investigated lasted from July to December, 1942. In addition the absences of another group, 33,500 in number, were investigated in less detail for the two years 1942 and 1943. The information brought together was restricted to certified sickness absence of two or more days, so the time actually lost through sickness was likely to be underestimated. The time ascertained amounted to 7.8% of the total working time. More than half of the women were married, and their sickness rate was 65% higher than that of the single women. As has long been recognized, an excess such as this would chiefly be due to the extra-physical and mental effort required for running a house. It was not due to the greater age of the married women, for in both groups the absenteeism tended to become less with age, reaching a minimum, with one exception, in women of 50 to 59. In the six months investigated every hundred workers showed, on an average, 24 cases of respiratory disease, 12 of digestive trouble, 10 of nervous symptoms, and 5 of "fatigue." One-eighth of the nervous disorders were organic and the remainder of the functional type, but there can be no doubt that some of the diseases of the digestive system had a psychological origin and should rightly have been included in the nervous group. The absences due to fatigue had been labelled asthenia, general debility, or general fatigue, and it was interesting to note that they were 136% more numerous in married women than in the unmarried. The nervous cases were 82% more numerous, while in contrast the respiratory cases were only 27% more numerous.

The report includes a large amount of detailed statistical information concerning sickness in relation to length of service, to the type of work performed, to shift systems, to the numbers discharged because of ill-health, and to other factors; and the investigators claim that the results obtained illustrate the importance of accurate and complete records of sickness absence as a necessary foundation for any sound system dealing with industrial diseases. As is pointed out in the preface to the report, the wartime extension of industrial and medical services has done much to prevent illness, but scientific evidence of the effects of environmental and other factors is lacking. It was for this reason that the Board decided that there was need for a detailed inquiry into the nature, distribution, and causes of sickness absence. The present report is a contribution to such an inquiry.

SILICOSIS IN BOILER SCALERS

Boiler scalers are exposed to two types of dust—the scale deposited from the water circulating in or outside the tubes, and the dust in the fire tubes, flues, or fireboxes. The first case of a pulmonary dust disease occurring in a boiler scaler was reported in this *Journal* by W. E. Cooke[1] in 1930 in a paper entitled "Pneumokoniosis due to Flue Dust." He found that, whereas the boiler scale contained 6.4% of insoluble siliceous matter, the flue dust contained 26.4%. A man aged 35, who had worked for 9½ years as a boiler cleaner, developed shortness of breath and cough. Skiagrams showed appearances of advanced silicosis. He died. Necropsy revealed generalized patchy fibrosis in both lungs, and tuberculous lesions in the right upper lobe. Cooke, however, thought that the fibrosis of the lung preceded the tuberculous infection by many years. In the following year Williams[2] reported six cases. Necropsy of one of these showed there was a diffuse "anthracosis" but relatively slight formation of fibrous tissue. Dunner[3] in 1943 described the clinical and radiological appearances in 12 boiler scalers who had complained of pain, shortness of breath, and, in two cases, of small haemoptyses; with Hermon[4] he gave an account in 1944 of a further five cases, four of which were complicated by pulmonary tuberculosis and one by a carcinoma of the lung. Last year Todd and Rice[5] reported fully the case of a man aged 40 who had worked for 14 years in his early life as a boiler scaler and who later developed shortness of breath. The skiagram showed a snowstorm type of infiltration of both lungs, equal in intensity from hila to periphery of the lungs.

In Cooke's analysis of boiler scale and flue dust the former contained 3.4% and the latter 27.2% of iron oxide, which is oqapue to *x* rays. After Doig and McLaughlin[6] had demonstrated reticulation in the skiagrams of electric-arc welders who had been exposed to fume containing much iron oxide, the cause of these *x*-ray changes was naturally sought for. Many cases of *x*-ray reticulation in welders have since been recorded, but the only necropsy was done following exhumation 2 years after death by Euzer and Sander.[7] It was found that the lung contained excess of iron and that no pulmonary fibrosis had occurred. Harding[8] has produced *x*-ray reticulation in rats by injecting "rouge" into the trachea, but histological examination of their lungs showed no fibrosis. McLaughlin, Grout, Barrie, and Harding[9] have studied the lungs of a silver polisher in whom *x*-ray reticulation had been observed. He died with post-operative bronchopneumonia; and, once more, histological examination disclosed the presence of iron particles but no fibrosis. In this man the medial layer of all the arteries in the lung contained a deposit of silver which could readily be removed with potassium cyanide. During life he polished silver with rouge (iron oxide). From this collection of material there seems little doubt that iron oxide causes changes in the appearance of pulmonary skiagrams but does not produce fibrosis of lung. The lung is essentially an elastic organ, and if its elasticity is impaired the man is likely to suffer from shortness of breath; it does not therefore follow that because there is no fibrosis there is no disability.

In a recent number of the *British Journal of Industrial Medicine* Harding, McRae Tod, and McLaughlin[10] report in great detail the clinical history and necropsy of a boiler scaler who died with a carcinoma of his right upper bronchus. This is the same case as the fifth one subsequently reported by Dunner and Hermon. He was aged 61, and had been employed as a boiler scaler all his working life since the age of 14. Six years before his death he had been in hospital because of dyspnoea and cough, and a skiagram at that time showed nodulation through both lung fields. In December, 1943, he was again admitted to hospital, and the same *x*-ray changes were observed, with an opacity at the right apex. Carcinoma was found post mortem. Sections of the lungs showed typical, solid, collagenous silicotic nodules that were pigmented, as those seen in the lungs of coal-miners. The lungs were incinerated at 500° C. and yielded 5.1% tawny ash. Iron formed 0.6% and silica 0.17% of the dry weight of the lungs. A sample of boiler scale taken from the type of ship's boiler usually scaled by this man contained 10.1% of iron calculated as metal and 8.6% total silica, probably present largely as silicate. A sample of flue dust contained 48.3% of iron and 6.1% total silica. It seems, therefore, that in boiler scalers the *x*-ray changes are brought about by a combination of iron oxide and silica. The post-mortem finding, however, clearly showed the presence of silicotic nodules in a man who had worked all his life as a boiler scaler. Logically, therefore, legislation ought to be introduced under the Workmen's Compensation Act to include boiler scalers in one of the silicosis schemes.

ACCIDENTAL SUFFOCATION OF INFANTS

The number of deaths in children in the United States attributed to accidental mechanical suffocation is increasing. Under 1 year 692 such deaths were recorded in 1933, and 1,333 in 1942. H. Abramson[11] points out that in the city of New York this accident accounts for more deaths in children than measles, scarlet fever, and diphtheria combined. It therefore presents a social problem of first importance. Abramson has analysed the figures in New York for a period of five years in infants under 1 year, who make up four-fifths of the fatalities. He discusses 139 cases—85% in infants under 6 months. The peak of fatalities from accidental smothering occurs in the winter, and the hours of danger are 3 to 9 a.m. In about one-sixth of cases the baby was "overlaid" in the mother's bed, and in the remainder was either in cot or pram, with blankets improperly applied, loose pillows unnecessarily decorative, or loose mattress coverings as the main lethal agents. In two-thirds the baby was found face down. Abramson sets out preventive measures based on his analysis. First it must be brought home to the medical and lay public that accidental smothering is a serious menace to infant life. Detailed care of the baby's clothes and of the baby's coverings in cot or pram must be exercised. "No infant should ever sleep on a pillow, but always on a flat mattress." It is also most important that the young infant be never left in a "face down" or potential "face down" position where there is a risk of a brief movement turning the head so that the face can be enveloped in the bedding. It is also important to pay careful attention to details of feeding, as some deaths follow a feeding time, as when a mother falls asleep while feeding her infant, which is then found smothered.

[11] *J. Pediat.*, 1944, **25**, 404.

What is not made clear in Abramson's analysis is whether post-mortem examinations were made in the cases he describes, for, despite circumstantial evidence that suffocation is the cause of death, pathologists often find unsuspected lesions. Helen Deem makes this point in her annual report for 1943–4 to the Royal New Zealand Society for the Health of Women and Children. In that country, out of 951 deaths in the first year of life, there were 16 in which accidental mechanical suffocation was given as the cause. Post-mortem examination had not usually been made, but in 2 infants it revealed an acute respiratory infection in one and a pathological heart condition in another. Deem makes the point that a mother who believes that her child had been smothered by a preventable accident is likely to suffer great mental torture and reproach. This might be relieved if a post-mortem examination were always performed when suffocation has apparently occurred. Is it not also in such infants that a large thymus is sometimes found? Despite the statistical discrediting of status lymphaticus as a factor in child mortality, it is certainly a "condition" sometimes found in the suffocated infant. May it not also be that mental defect plays a part in the story—a part which even necropsy will not reveal? Head and chin raising movements become established and controlled between the fourth and sixth months. In the mentally defective baby such movements may well be delayed and thus increase the risk period for suffocation. Abramson has certainly underlined a problem of some importance, but without pathological details the issues tend to be too simplified. Perhaps it might be made an object for study by one of the new university departments of child health.

ROLLIER AND SUNLIGHT

A few months ago the seventieth birthday of Prof. Auguste Rollier was celebrated in a French-language Swiss medical journal.[1] Rollier's name is known throughout the world for the sun treatment of non-pulmonary tuberculosis. He began his work at Leysin in 1903 at a time when operative treatment had for some years been the rule for cases of so-called "surgical" tuberculosis—of bone and joint, of glands, and of the kidneys. The results of operation, more especially in bone and joint cases, were unsatisfactory; miliary tuberculosis and sinuses were common sequels. At Leysin Rollier showed that properly graduated exposure to the sun built up the resistance of his patients to their disease, healed their sinuses, and arrested their lesions. The results he achieved led to the erroneous view that heliotherapy is a specific cure for non-pulmonary tuberculosis; it is merely an adjuvant treatment, though a most valuable one, and must be combined with suitable orthopaedic apparatus for immobilizing the affected bone or joint. Rollier always recognized this and combined heliotherapy with conservative methods of treatment—methods which had been employed at Berck-sur-Mer for about 20 years before he began work at Leysin.

Rollier's method has been described as the "cure of altitude and exposure to the sun"; and the Swiss mountains have the advantage both of a clear atmosphere and of many hours of sunshine. But there is some divergence of opinion about the type of climate best suited to the tuberculous patient. The late Sir Henry Gauvain, a pioneer of heliotherapy in this country and always an admirer of Rollier and his work, thought the English climate in spring and summer was ideal for sun-treatment owing to the contrasts of light and shade. Gauvain shared Rollier's enthusiasm for the use of the sun's rays for his patients with non-pulmonary tuberculosis, the treatment being given only to those who could respond with pigmentation. Interest soon spread from natural to artificial sunlight, and after a period of uncritical enthusiasm the latter was finally accepted as a substitute which had a place in the treatment of non-pulmonary tuberculosis. Rollier has won a place in the history of therapeutics, and we join with our Swiss colleagues in the tribute paid to him.

LONELY OLD AGE

The medical aspects of old age, now widely recognized, are inevitably bound up with the social aspect, which recent events have emphasized. It has been suggested[1] that the Services Convalescent Homes might be converted after the war into rest homes where aged persons could spend three to four weeks each year. But this only touches the fringe of the problem, for in many instances a permanent home is needed. The Friends Relief Service have formulated and put into action what appears to be a more excellent way.[2] Their work for old people arose in the first instance during the period of heavy air raids, when there were scarcely any official arrangements for their removal from the target areas. At that time such hostels were regarded as merely a temporary expedient, and those who ran them did not realize that they had embarked upon a long-term social work of increasing importance. The main social problems of the elderly at the present time are loneliness and neglect. The large institution is no answer to the needs of the aged, and their dread of ending their days there is very natural. The experience of the Friends Relief Service is that the optimum size for their hostels is for 25 to 30 persons with occasional larger hostels to hold up to 35, where special facilities, such as expert nursing, could be provided. Every detail of the problem involved has been carefully considered, and clearly described in their booklet. Another scheme in operation is the Hornsey Housing Trust, which is now being expanded in other parts of the country as the Hill House.[3] The plan is to turn residential houses now unsuited for family life into one- or two-roomed apartments, with an alcove with running water and a gas stove. The rooms are of good size and suitable for the large old-fashioned furniture which many old people possess. The scheme also provides privacy for those who feel like the old lady who said, "I don't neighbour." All these plans are coping with a real problem, which unsolved leaves the medical profession handicapped, if not impotent, in their treatment of the isolated aged.

We much regret to learn of the death of Sir James Barrett, F.R.C.S., who was President of the British Medical Association when it met in Melbourne in 1935, and Chancellor of Melbourne University 1935–9.

IS MEDICAL EDUCATION SCIENTIFIC?

AN EXPERIMENTAL APPROACH

BY

D. H. SMYTH, M.D., M.Sc., Ph.D.

"No general principles have been imparted to him."
F. M. R. WALSHE.

This quotation, taken from an article on "Some Principles of Reform in Medical Education,"[1]* seems best to sum up its author's criticisms of the present educational system for the medical student. The same view has frequently been expressed by other writers on the subject, and is one of the emphatic conclusions in the report of the Interdepartmental Committee on Medical Schools. Furthermore, the faults in the teaching are often said to be accentuated by the examination questions, which demand too much knowledge of detail and not enough knowledge of general principles. In defence of the existing teaching it is claimed that general principles can be imparted only by teaching certain parts of the course in considerable detail, and that a knowledge of general principles not based on knowledge of detailed processes is impossible. The solution to the difficulty is not made easier by the fact that few of those who discuss the problem ever state specifically what they mean by "general principles." As a result there is apt to be much discussion with little progress in putting forward a remedy, since in any particular instance it is very difficult to decide whether or not general principles have been learned by the student in addition to the factual information which he has acquired. The present article seeks to make a contribution to this subject by describing an experimental approach to the problem—namely, the collection of some evidence as to how far general principles have been grasped by the medical student at a particular stage in his education.

In carrying out the experiment I have been guided by certain considerations. A study of the criticisms of medical education shows that it is much easier, though probably less helpful, to criticize those parts of the curriculum for which one is not personally responsible or in which one is not deeply interested. On the other hand, such criticism, in sufficient detail to be of much value, is tempered by consideration for the feelings of one's colleagues and by an unwillingness to seem to interfere with the work of another department. The experiment was therefore planned so that it dealt mainly with that part of the course for which I was partly responsible—i.e., the preclinical training in physiology. It is inevitable, however, that earlier parts of the medical studies, and also the teaching in the schools, must share the responsibility for the level of the students' education. A second consideration was that the "principles" chosen for investigation should be as general as possible, and, while it was the purpose to relate these specifically to physiology, it was intended that they should be common to most fields of scientific activity.

Experimental Material

The subjects of the experiment were 54 medical students studying for the second M.B. examination of London University as internal students. These students had all completed the first M.B. examination or its equivalent by July, 1943, with the exception of two who passed first M.B. in Dec., 1943. All therefore had had at least several years' exposure to a "scientific" education. The group had studied physiology more or less intensively since Sept., 1943, along with anatomy and biochemistry. In physiology, the subject of the present test, they had had three different teachers, all with a moderate amount of research as well as teaching experience, so that theoretically the atmosphere for a scientific education was "set fair." So far as can be judged the students were of good average ability, and it would be estimated, by comparing them with students of other years, that the majority will pass the second M.B. at the first attempt, and some will distinguish themselves. The average age was about 19, but a small number, somewhat older, had more experience than the rest: one had a Cambridge honours degree in natural sciences, one had several years' experience of school teaching, and one had held a post connected with urban health administration.

Nature of the Test

In a sessional examination held in July, 1944—i.e., three terms after starting the study of the second-year subjects—a compulsory question of a special nature was included in a three-hour paper along with five other questions of the more usual kind. Four questions out of the other five had also to be answered. The compulsory question was as follows:

> Explain briefly what meanings you attach to the following terms, and illustrate these by examples taken from your knowledge of physiology:
> (*a*) hypothesis
> (*b*) law of nature
> (*c*) controlled experiment
> (*d*) empirical method
> (*e*) percentage error
> (*f*) inductive and deductive reasoning

It should be stated that during the session I had given a course of lectures which had terminated in March, 1944—i.e., a considerable time before the idea of asking such a question had occurred to me, and the matter had not been mentioned to other members of the staff who were engaged in giving courses of lectures, so that there was no question of the students being told either more or less about general principles than would otherwise have been the case. The six sections of the question were chosen without very special thought, but were meant to give the student an opportunity (1) to show what knowledge he possessed about general scientific principles; (2) to show how far he could recognize in the subject of physiology those scientific principles; (3) to show his ability to use words accurately and to define terms which were in current scientific use. It was hoped that the easier parts of the question would be within the capacity of most of the students, while the more difficult sections—e.g., inductive and deductive reasoning—would try out the best. In this way it would be possible for every student to give some demonstration of his ability.

Results

It was not an easy matter to analyse and present the results. Clearly a numerical assessment is not of very great value, as no standard exists as to what a medical student should know of such things at such a stage. Furthermore, I do not feel specially competent to make such an assessment, and indeed would be somewhat unwilling to stand a cross-examination on the meaning of the terms by a severe critic. The results have therefore been analysed by picking out what answers seemed to show a reasonable knowledge, a fair knowledge, or no knowledge at all of the subject. In order to demonstrate what was considered a reasonable knowledge, etc., samples of each category are given. These are not necessarily the best or worst answers, but are meant to be average replies. In most cases it is more instructive to give a larger number of examples of wrong answers than of right, on account of greater variety in the former. The nature of the questions made it convenient to vary the classes into which the answers to the different questions were divided. The original intention had been to place emphasis on the illustration of the terms by examples from physiology. Actually it was found that so few of the answers included examples that the analysis was made on the basis of the definitions, although it was clear that in many cases the candidate had in mind physiological processes. Some brief comments on the illustrations chosen are given in a later section. It is convenient to present separately the analyses of the answers to the different parts of the question.

(a) Hypothesis

It might have been expected that the meaning of the expression would be well known, as it is at the very basis of scientific progress. This, however, was by no means the case. The answers were not easy to classify; and the following division was used. The figures show the number of answers in each class and also the percentage which this forms of the total number of answers.

Class I:	Satisfactory explanation	19 (35%)
„ II:	Probably knows, but does not explain clearly	22 (41%)
„ III:	Probably does not know	7 (13%)
„ IV:	Definitely wrong	5 (9%)
„ V:	Did not attempt	1 (2%)

---

* *British Medical Journal*, Feb. 5, 1944, p. 173.

Of the 19 put into the first class only five mentioned the relation between a hypothesis and a theory. Examples of the classes:

Class I.—"When the observed phenomena have been explained in the light of known facts without the explanation being proved by a series of controlled experiments then the explanation is said to be a hypothesis. As soon as a hypothesis has been demonstrated to be correct by well-balanced controlled experiments or by logical deduction from other observed facts then the hypothesis becomes a theory until it is eventually disproved in the light of further experiments."—"A hypothesis is a suggested explanation of known facts. It may or may not be possible to test the truth of a hypothesis by experiment."

Class II.—"A hypothesis is a series of statements which are set out to form a new law, but which have not yet been proved by experimental evidence."—"This term is applied to any theory put forward which cannot be absolutely proved by scientific means available."

Class III.—"A hypothesis is a statement as to the function of a certain thing, the reason for which has been deduced from experimental or theoretical work, but which has not actually been demonstrated by experiment."

Class IV.—"Hypothesis means 'data,' and may be illustrated as follows: Analysis of inspired and expired air shows that the nitrogen content of expired air is greater than that of inspired. Reasoning as to the cause of the increase in nitrogen content may involve respiratory quotient, etc., but the fact remains that by hypothesis the nitrogen content in expired air is greater than in inspired."

(b) Law of Nature

It was evident that very vague ideas were held as to the meaning of the expression "law of nature." No one seemed to have a clear conception of a law of nature being a description of some property of matter which is exemplified by a large diversity of things or processes, and which has been formulated as a result of observation and experiment. The majority had an idea of inevitability as being the criterion of a law of nature rather than the idea of the law of nature being a generalization. It was found possible to classify the answers into five groups, as follows:

Class I:	Those who *probably* had some more or less correct idea	4 (7%)
„ II:	Those who *possibly* had some more or less correct idea	14 (26%)
„ III:	Those who *probably* had not anything approaching a correct idea	11 (20%)
„ IV:	Those who *certainly* had not a correct idea	19 (35%)
„ V:	Not attempted	6 (11%)

Class I.—"A law of nature is a general statement of a large number of phenomena which are controlled by the same factor."—"A law of nature is a statement concerning a sequence of events which so far has not been shown to vary."

Class II.—"A law of nature is a correlation between a large number of facts."—"A law of nature is a statement (by man of course) of what universally occurs in a certain set of fixed natural conditions."—"A law of nature predicts the action which always occurs in a given set of circumstances."

Class III.—"A law of nature is another name for the principle of the conservation of energy."—"A law of nature is a law by which a certain function or action takes place and can be proved to take place without exception in the normal state."

Class IV.—"A law of nature is an escapable occurrence not under the control of the human mind."—"When a person dies after his normal span of life nothing can prevent him doing so. This is a law of nature."—"A law of nature is a general axiom that holds good on *a priori* grounds."—"A law of nature is a phenomenon which cannot be explained."—"A law of nature is one which is fundamentally true and natural and therefore does not have to be proved in order to show that it is correct."

(c) Controlled Experiment

The results of this were more readily analysed, as it was relatively easy to see whether or not the candidate had grasped the principle of studying a system containing a number of variables by means of suitable controls. It was also encouraging to find that most of the candidates understood the meaning of the term and were able to give appropriate examples. The results are classified as follows, together with numbers and percentages:

Class I:	Those who obviously knew	44 (81%)
„ II:	Those who did not realize the principle involved in "control"	9 (17%)
„ III:	Did not attempt	1 (2%)

Class I.—"A controlled experiment is an experiment designed to discover the effect of a particular factor in a series of events, by eliminating this factor in one experiment and performing another experiment in all respects exactly similar except that the factor in question is not eliminated."

Class II.—"This is an experiment done under the best possible conditions; everything as far as possible is perfect and conditions are controlled."—"A controlled experiment is one in which all the factors are controlled—that is, all the factors involved are able to be controlled, so that every result may be anticipated from knowledge of the amount of a certain factor which is being used."—"A controlled experiment refers to an experiment which is performed usually on an animal with certain conditions imposed and under the control of the investigator."—"A controlled experiment is an experiment in which normal reactions are obliterated in order to show some underlying reaction normally suppressed."—"A controlled experiment is one in which the patient's life is not radically shortened by the operation performed, and in which therefore observations may be made over a considerable period of time."

(d) Empirical Method

The definitions of empirical method were also fairly easy to classify, as it was evident that only a very small number had a correct idea of the meaning of the term, while the majority attached a definitely erroneous meaning to it. Of the latter there were two main groups: first, those who thought that an empirical method was one in which relative quantities and not absolute ones were being measured; and, secondly, those who regarded an empirical method as a simplified method or a method intended to give only approximate results. The former group evidently derived their idea from the term "empirical formula" used in chemistry. Some of those in the second group contrasted empirical method with controlled experiment. The answers were divided into the following groups:

Class I:	Those who clearly knew	4 (7%)
„ II:	Those who possibly knew, but did not express their ideas very clearly	10 (19%)
„ III:	Those who definitely held an incorrect view	29 (54%)
„ IV:	Did not attempt	11 (20%)

Class I.—"Empirical method, common in clinical practice, refers to a procedure which is adopted according to certain set rules, without a true knowledge of the scientific basis. It is often the outcome of years of experience, of trial and error, and final success."

Class II.—"An empirical method is a method found out by experiment; it is an experimental method."—"A method which can be used for all similar occasions and circumstances to convey certain information, the reason for which may not be known."—"An empirical method is a method which has observable effects which are as yet unexplained but are always the same."

Class III.—"The empirical method of conducting an experiment is to determine the relative proportions of the substance present or of the effects observed. It does not give the actual results by weight or quantity."—"The empirical method is one employed to give a relative assessment of facts without having an absolute method or standard."—"An empirical method is a rough estimate of the results of an experiment. Here the experiment is not carried out under conditions of great accuracy."—"This is a calculation or experiment performed on the simplest possible basis."—"An empirical method is a method of calculating a result from a few basic facts without any effort to prove by experiment."—"An empirical method is a basic method. It would set out to establish a basic assumption or to prove again a basic proven fact."—"An empirical method is designed to show the interrelationships of facts."—"A method, experimental or theoretical, which can be applied only with minor modifications to a group of subjects."

(e) Percentage Error

This was a very straightforward question, and, as might be expected, the majority of the answers showed an appreciation of its meaning. Those who were not classified in Class I mostly failed because they did not attempt to define what exactly the percentage consisted of. They would probably have known had they been examined orally. The numbers in the classes were as follows:

Class I:	More or less correct answer	32 (59%)
„ II:	Expression not defined clearly, or some misconception or absurdity expressed	19 (35%)
„ III:	Not attempted	3 (6%)

Class I.—"Percentage error is the amount that a particular result differs from the average of a number of results expressed as a percentage of that average."

Class II.—" Percentage error is the limit of inaccuracy of the result of an experiment."—" Percentage error is the error which is got in an experiment. The error of every person is different, and the personal error of an experimenter is always worked out."—" The percentage error is the expression of error as a percentage of the result. The percentage error should not be allowed to rise above the experimental error expressed as a percentage."

(f) Inductive and Deductive Reasoning

Admittedly this was a difficult question, and it was not expected that many good answers would be obtained. It was added rather for the purpose of giving the best students an opportunity to show their knowledge, and of testing the response of the others when dealing with a matter which was rather outside their capacity. The answers corresponded with the expectation. No one used the familiar expressions of reasoning from the particular to the general in the one case, and from the general to the particular in the other. The most one could look for was the small number who appreciated that there were two types of reasoning, even though they did not define these clearly or attach the correct names to them. The answers were classified with some difficulty into the following groups:

Class I:	Those who described two different types of reasoning, even though the labelling of these was incorrect	5 (9%)
„ II:	Those who defined one or other of the terms in anything approaching a correct manner	7 (13%)
„ III:	Those who had no clear idea about the meaning of the words	32 (59%)
„ IV:	Did not attempt	10 (19%).

Class I.—" Inductive reasoning is reasoning from knowledge of the theory of a certain subject and not from practical experience. Knowing the theory of a subject, reasoning may be employed to determine the result of a certain experiment before it is actually carried out. Deductive reasoning occurs as a result of an experiment—that is, from the results of an experiment a new theory may be deduced."—" The cycle in the scientific process is: experiment—deduction—theory—induction—experiment."

While it is evident that in both cases the terms " induction " and " deduction " have been interchanged, these answers show an appreciation of the processes involved.

Class II.—" Deductive reasoning is logical reasoning predicting the result from knowledge already obtained."

Class III.—" Inductive reasoning is reasoning that from a certain action another action ought to secure result. Deductive reasoning is reasoning that, because a certain phenomenon has been observed, a certain action has caused it or controlled it."—" Deductive reasoning is employed when correlating a number of facts in order to produce a satisfactory conclusive statement concerning these facts and their relation to each other. Inductive reasoning is employed when proving a dogmatic statement."—" In inductive reasoning you see in a fact another fact. In deductive reasoning you deduce an answer from several facts."—" Deductive reasoning is a means of arriving at a conclusion from a set of known facts. It does not establish anything that could not have been known previously having regard to the facts. Inductive reasoning is a method of establishing a new fact without previous knowledge of it."—" Inductive reasoning is one built up without facts, whereas deductive reasoning is the building up of a theory from certain observed facts."—" Inductive reasoning consists of soaking up other people's ideas regardless. If, however, one reasons deductively, step by step, checking points, references, etc., one will have a much better understanding of the subject, though it will have cost you much more energy."

Physiological Illustrations of the Terms

As already stated, it had been intended that this should be the most important part of the question, but it turned out that this was not in the minds of the candidates. Probably had the question been better worded this might have been avoided. It is clearly of little use for the student to know definitions of principles unless he can recognize these principles in the detailed processes and results of each particular science. A number of examples were, however, given, and sometimes were contained in the definition. It was instructive to see that where correct examples were given these were often obviously taken from work in the practical class rather than from textbooks or lecture notes. Empirical method was illustrated in one case by methods of staining blood films. Percentage error and controlled experiment were mostly illustrated by examples from the practical class in biochemistry. From the scanty data obtained, it would be tempting to draw the conclusion, even if inadequately supported, that the laboratory rather than the lecture theatre is the correct place to learn an appreciation of scientific method. It would be interesting if further data were available on this very important aspect of scientific training.

Conclusions

The examples given above speak clearly enough for themselves. It appears that a large number of students have only the vaguest ideas on expressions and terms which are in everyday use in scientific work, and indeed which would seem to be at the basis of the scientific method. Equally disturbing was the fact that of those who could define the terms more or less correctly, very few were able to produce examples taken from physiology which would illustrate these. Both these findings seem to bear out Dr. Walshe's contention that in the teaching of the student there is too much imparting of facts and too little imparting of general principles.

In this investigation certain general principles have been selected and students tested for their knowledge of these. A further question now arises. Is it really important that the medical student should be able to deal with matters of this kind? This is not altogether easy to answer. On the one hand, it is easy to see, for example, that persons who are going to be responsible for public health work should understand clearly what is a controlled experiment, so that they may not be too easily influenced by figures claiming to represent the effect of various factors on the health of the community. On the other hand, one knows that there are many indispensable people in all departments of the medical services who could not define what they mean by inductive reasoning. There are also probably many skilled laboratory workers and first-rate research workers who would have difficulty in defining scientific conceptions of a general nature; and, indeed, many of those who make the greatest contributions to scientific research make very little use, in their writing and talking, of abstract conceptions of the kind which we are discussing at present. Obviously there is much need for careful thought as to what are the educational needs of the scientifically trained section of the population.

But, assuming that some knowledge of abstract scientific method is desirable in medical students, how is it to be achieved? There seem to be two possibilities. The first is that the scope of the teaching might be reduced so that less time would have to be spent in acquiring facts, that teachers might be encouraged to interest the student in the more general principles of scientific method, and that examination questions might be framed so that time spent by the student in thinking on these things would pay dividends even in the short period of 18 months. This is the method one would like to see tried. There is, however, also a second possibility. To an already overloaded curriculum might be added a new subject called " Scientific Method," for which doubtless a suitable " Aids " and " Synopsis " would quickly be forthcoming. The student would add to his tasks the learning of a new series of terms and a new jargon, with still less time to think over their relation to what happened in the laboratory or at the bedside. In this case the teacher might be excused for having some misgiving " that the last state of that man would be worse than the first."

The Scottish Council for Health Education (which was set up in July, 1943, by the Secretary of State for Scotland to cover the whole field of health education) held its second annual meeting in the City Chambers, Edinburgh. Bailie Violet M. C. Roberton, LL.D., chairman of the Council, presided, and warmly welcomed Dr. Arthur Massey, chairman of the Central Council for Health Education. The report of the Executive Committee and the audited accounts for 1944 were adopted, and it was noted with satisfaction that 51 of the 55 major local authorities in Scotland were contributors to the Council's funds. Despite many difficulties the Council's work steadily advanced in 1944. Nearly 40 leaflets and booklets on a variety of health subjects had been published and printed in Scotland, and it was reported that within the last few months nearly three-quarters of a million of these leaflets, etc., had been ordered by the local authorities for free distribution to the public. There was ample evidence of a widespread interest in health education, and strenuous efforts were being made to satisfy, foster, and sustain that interest.

Correspondence

Activities of Officer Prisoners of War

SIR,—It gave me peculiar pleasure to read the very interesting paper by my friend Capt. A. R. Dearlove on his investigations into the activities of officer prisoners of war (March 24, p. 406). As an expression of his own activity the paper speaks for itself. When about a year ago Dr. John Harkness wrote (April 22, 1944, p. 568) " the very large majority of our returned prisoners of war will be problems for their lifetime " his letter called forth vigorous protests from two medical officers who had been prisoners of war and one who is still in enemy hands. To these protests I should like most emphatically to add my own. But however well founded these protests may be, they are, after all, only opinions. It may be that we, without realizing it, are ourselves " problems "! Capt. Dearlove, therefore, has done a good service, quite apart from the value of his investigation on the problems of the use of leisure, in approaching this question more objectively.

It would have been interesting had his last two questions (concerning physical and psychological impairment) been so couched as to elicit whether the men thought the impairment was permanent, but even without this it is interesting that not much more than a third of them consider themselves to be impaired, physically or psychologically. Some psychologists would maintain, I fancy, that this approximates to the number in the general population of those liable to neurotic reactions in unfavourable circumstances. The grouping by length of captivity yields intriguing results, in that the 2-year group had much the highest " psychological impairment "—55% as compared with 38% in the 4-year group and 41% in the 3-year group. This might be taken to indicate that the impairment tends not to be permanent and that many men achieve adjustment even under the continuance of the adverse circumstances. It is unlikely, I think, though possible, that there is a higher incidence of neurosis among the North Americans (who form the bulk of the 2-year group) than among the presumably predominantly Anglo-Saxon British and Australasians. Complex factors are, of course, operative, and no single or simple explanation is likely to be sound.

There can, I think, be little doubt that Capt. Dearlove's general conclusion is sound, that the " 'P.O.W. neurosis' is similar to the commoner 'war neurosis,' which, according to Gillespie, arises at a superficial level and will presumably disappear when the conditions causing it are removed." This last point needs a little extension by those of us who have seen a good deal of the already repatriated P.O.W.s. Major P. H. Newman put the matter succinctly in his letter (Feb. 3, p. 163), which concluded thus: " The repatriate wishes to rejoin the queue where he left it years ago, not at the back." " I thoroughly agree with the final paragraph," writes Capt. C. Donald (Feb. 17, p. 235), referring to Major Newman's letter. " The 'square deal,' or lack of it, is, of course, the excuse given for all discontent throughout the country, and unfortunately many ex-P.O.W.s harbour a legitimate grouse." A legitimate grouse is not a neurosis! *Verbum sapienti.*—I am, etc.,

E. R. C. WALKER.

Aberdeen.

Relief of Oesophageal Obstruction

SIR,—In the interesting leader on the relief of oesophageal obstruction (March 17, p. 373) I rather gathered that the writer is a little half-hearted about the method of self-dilatation by bougies which he mentions in reference to one of my own cases (*Brit. J. Surg.*, 1943, **30**, 344).

Your readers may be interested to know that the patient to whom the leader particularly refers is now completely well and tells me that he has not the slightest difficulty in swallowing. Recently he had luncheon with a party of visiting surgeons at the Postgraduate School and ate, without the least difficulty, the same lunch and at the same rate as the other guests. He informed me that he had not used a bougie since November, 1943, and that was only done at my especial request. It is now five years and two months since treatment by bougies was first started at a time when he had not swallowed by the normal channel for nineteen years.

There are many other examples, and in my second Haliburton Hume Memorial Lecture published recently (*Newcastle med. J.*, 1945, **22**, January) I have referred to some of the late results.

The first case in which I ever employed this method was a patient whom I saw suffering from what looked like acute mediastinitis following on dilatation through the oesophagoscope. Thereafter treatment was rather long and trying, but he came to see me in August, 1944, ten years after beginning the bougie treatment, and was able to state that he could swallow any kind of food without difficulty. Occasionally, about every three months, he still passes a bougie with ease.

Another case of particular interest was that of a female patient who was admitted under my care in August of 1935 with what proved to be an obliteration of the oesophagus following the swallowing of a quantity of hair lotion. For six months she had been nourished through a gastrostomy, and during that time had not even been able to swallow her own saliva. A way through the obstruction was established by the retrograde method, and thereafter treatment by bougies, which the patient herself passed, was continued. At the time of writing, seven years and four months after leaving my care, the patient reported herself as perfectly well and without difficulty in swallowing of any sort. She was then married and doing full-time war work.

A man who came to us in desperation, and who despaired of relief by any means other than some dramatic operative intervention, was treated by bougies, and in October of 1942, six years after the commencement of that treatment, he was very well and actively employed as a works manager, though he did require to use a bougie from time to time.

I have employed the direct attack through an open thoracotomy and should not hesitate to do so if all else failed, but my experience with the use of bougies and the necessary correlated measures has taught me that only in very few cases is the direct method likely to be required.—I am, etc.,

Infant Deaths

SIR,—The reference to infant mortality in Dr. W. J. Martin's article (March 17, p. 363) and also the reference to infant mortality in New York City in your leading article (March 10, p. 337) move me to make certain comments and suggestions.

It is stated that practically the whole of the increase in the infant deaths in New York " occurred during the first month of life and mainly between the ages of 10 days and one month, the causes responsible being diarrhoea and congenital malformations.". Dr. Martin comments in his analysis: " A matter for concern is the steady rise in deaths due to injury at birth. . . . A similar trend has been shown by the U.S.A., where the mortality from injury at birth rose from 3.9 in 1920 to a peak of 5.3 in 1930 and then declined slightly to 4.8 in 1939. It seems rather ironical that, despite the efforts to reduce mortality, the death rate from violence should increase." Dr. Martin groups together deaths due to congenital malformations; congenital debility; premature birth; injury at birth.

I suggest that a post-mortem examination be carried out as a routine measure in every institutional death under 4 weeks and wherever possible in private practice also. Much surprising information might be gleaned in this way which would be of real value. To illustrate this point a few recent cases in my own practice might be quoted.

(1) A baby delivered with forceps after a long second stage died on the 10th day. There was ample breast milk and the child seemed to be doing satisfactorily for nearly a week. Death was thought to be due to cerebral haemorrhage. P.M. showed atelectasis. (2) A premature twin flourished for a few days, then vomited all feeds and gradually lost weight. Examination by a paediatrician on the 11th day detected no sign of respiratory or intestinal infection. Special food and methods of feeding were prescribed, but the child died on the 15th day. P.M. revealed an incomplete rupture of the tentorium with some venous oozing and congested areas of the lungs from which staphylococci were demonstrated. (3) Two babies delivered the same day by Caesarean section faded out without any cough or obvious signs of respiratory infection within a few hours of each other when 10 days old. Both were found on P.M. to have advanced pneumonia with pneumococci demonstrated in every smear. (4) One woman had two babies each with a very easy and rapid " second stage." The first died on the 3rd or 4th day. The second died on the 10th day. A P.M. on this child showed an extensive

cerebral haemorrhage, though the birth was easy and the perineum appeared to offer no resistance or pressure to the head.

I think it possible that many others will make equally inaccurate diagnoses, and a P.M. would be valuable for accurate statistical purposes, if for no other reason. Healthy mothers under regular ante-natal supervision receiving priority eggs, milk, and vitamins ought to be able to produce healthy viable babies and a plentiful supply of good milk. Are statistics available showing the proportion of breast-fed and artificially fed infants in this tragic death roll? I have the impression—though I have not attempted to check the numbers—that a large proportion of mothers regularly attend the clinics to have their babies weighed and to collect "dried milk" and vitamins. One wonders if any real attempt is made to encourage natural feeding. I have been asked by a very intelligent young lady early in the third month of her first pregnancy what artificial food was best for her baby!

There appears to be a widespread habit of firmly pinioning young babies with the intention, I am told, of preventing them sucking their thumbs, scratching their faces, or damaging their eyes. In my opinion this custom has probably killed many thousands of babies during the past few years. A muscular young nurse rolls the child in a firm shawl or woollen blanket with the arms extended over the abdomen. A final twitch tightens the blanket and compresses the chest. The corner of the blanket is then securely tucked in and the helpless infant, as immobile as a mummy, is placed in its cot usually on the right side. If the binder is applied as firmly as the constricting shawl, abdominal breathing is almost impossible and thoracic breathing must be very shallow and extremely exhausting. If doctors in charge of maternity units will make an unexpected examination of all "binders" and test the lack of freedom of the infants' arms and the amount of pressure on the chests, some useful information may be gathered, and if this cruel and pernicious custom can be stopped I am sure many lives can be saved annually. If a necropsy is performed on all babies thought to have died as a result of congenital debility, premature birth, or injury at birth I think it probable that many will be found to have right-sided hypostatic pneumonia, or atelectasis. Possibly tight abdominal binders may contribute to excessive posseting, vomiting, and other difficulties in feeding.

Twenty to twenty-five years ago (my personal experience does not go further back) one would receive a handywoman's call to a dirty house devoid of all sanitary conveniences or conveniences of any kind, to deliver a woman of a large baby. After a struggle a bruised and shocked baby would be delivered, and with very little attention it usually survived and thrived. Nowadays after conscientious ante-natal care an easy forceps delivery takes place under ideal surroundings, the baby showing no signs of trauma yet for no obvious reason it wilts and dies. Killed by kindness?

Since writing the above I have discovered the following in Ashby's *Health in the Nursury,* published in 1899:

> "The binder should be of soft flannel and must not be applied tightly; its object is to keep the dressing on the navel in place, and not to bind the baby up; it will certainly do harm if it is tight enough to compress the chest or stomach." And again: "Customs, however foolish, die hard, and there still seems to be a legion of nurses who implicitly believe in the necessity of bandaging up the body of an infant like a mummy, and securing the roll of flannel after being pulled tight, with a row of stitches. It is surely not necessary to say that such bandaging is harmful, for any compression of the abdomen and chest prevents the proper expansion of the lungs, interferes with the circulation, and increases the risk of 'rupture.' We must bear in mind that the size of the abdomen alters in circumference from time to time during the process of digestion."

To summarize. I do not claim to have "proved" anything, but I have recorded certain observations in the hope that it may lead to widespread investigation in the nursing of infants and help to check the wastage of child life. I suggest that a necropsy should be a routine measure to verify the cause of every neonatal death. That an investigation be immediately carried out in every maternity unit and on the "district" into the matter of tight "binders" and "pinioning." The arms cannot be secured within a shawl without some constriction of the thorax and embarrassment of respiration. It might also be noted whether or not it is customary for the babies to be left more frequently and for longer periods on their right sides than on the left. It is my belief that thousands of babies are being killed by these methods of nursing and their deaths credited to congenital debility, premature birth, and injury at birth. If this can be demonstrated and prevented I anticipate a very great improvement in the following years' record of neonatal deaths.—I am, etc.,

Huddersfield. S. H. Waddy.

Newer Concepts of Breast-feeding

Sir,—Dr. M. Witkin's "newer concepts" (March 31, p. 441) appear to me to be wrong, first, because they are based on a misconception, and, secondly, because they make breast-feeding unduly complicated and difficult. I find it hard to believe that if a duct is blocked in the nipple a little massage, as described, will unblock it if the suction of the baby will not. The *vis a tergo,* surely, is infinitely less than the *vis a fronte!* If attempts are made to pull a happily sucking infant off the nipple, one realizes the suction pressure is very great indeed.

Breast-feeding is largely an emotional business, and anything that makes the mother think it is difficult is to be deplored. If a mother wishes to feed her child—and in my experience most of them do—nothing can stop her doing so except folk, and it really is extraordinary how folk try: the sick visitor (the chief offender), the mother, the mother-in-law, neighbours, friends, the nurse, the doctor, and the husband, in that order, are the chief enemies. The sick visitor comes along, weighs the baby, says it has lost weight, and the seed of doubt is sown. At the next visit complementary or supplementary feeding is suggested. At the third visit some corporation food and a bottle are introduced, and, finally, the first artificial feed is administered.

On a housing estate there were eleven mothers feeding their babies artificially, and one (mine) on the breast. The sick visitor tried to introduce the bottle to my mother, but I won. If a mother wishes to feed her child, and she is told that it is easy and is encouraged, and she is warned *carefully* against listening to folk, and if necessary is protected from them, then nothing can stop her feeding it, in my experience.

Finally, Dr. Witkin's success with breast-feeding is probably due to his enthusiastic advocacy and not due to his newer concepts. I find I get excellent results with a completely different technique—namely, leaving it to the mother to feed the baby in the manner she finds easiest and best for both herself and child, and doing my utmost to protect her from folk.—I am, etc.,

Rotherham. Eric Coldrey.

Sir,—Having read another helpful article on breast-feeding (March 31, p. 441), I wonder if I may comment on my own experience of happy and successful breast-feeding?

We have three small boys, and I have reared them without benefit of bottles (I just keep one for a mascot). Even when drinks of water were indicated these were given from a spoon, and the boys were weaned to the spoon by the time they were 7 to 9 months old. I agree whole-heartedly with the statement that the mother "should be alone in her room and not disturbed, in order to give undivided attention to her babe." I associate unsuccessful feeds with: (1) argument or even conversation with grown-ups present at a feed; (2) anxiety about fulfilling appointments or domestic duties between feeds or immediately after them; and (3) keeping an eye on the other children. I have been lucky to have had enough domestic help to reduce these difficulties to a minimum. Of course I know of women who are not interested in feeding their babies themselves, but for others I suggest that success or failure with breast-feeding at home depends on the presence or absence of domestic help.—I am, etc.,

Belfast. Isabel Wilde.

Flour in the Loaf

Sir,—Mr. H. C. H. Graves, chairman and managing director of Vitamins Ltd., disputes (March 31, p. 460) the accuracy of certain statements made by Lord Portsmouth in the debate in the House of Lords on Feb. 28. I submit the following evidence in support of Lord Portsmouth.

The constituents of the wheat grain which are in question are those derived from the wheat germ. Their only source is home-grown wheat. The germ has been removed from imported wheat in the country of its origin.

At the outbreak of war flour prepared from home-grown wheat constituted only 13% of our home consumption (*vide* leaflet issued by Ministry of Food, May, 1941). The supply of wheat germ, therefore, must have been and remains extremely limited. Sir Edward Mellanby (*British Medical Bulletin*, Nos. 10 to 11, 1944) writes: "The bread eaten before the war was made of a low-extraction flour, 70 to 73% of the berry, and consisted entirely of the endosperm, while the bran, aleurone layer, scutellum, and embryo were extracted by the millers" and sold for purposes other than human food. Mr. Thomas Fairbrother, an accredited champion of the millers, in the *Medical Press and Circular*, May 13, 1942, declared that "It was the general pre-war custom of the trade to separate the germ from the middlings, which were to be fed to cattle. The germ was separated by rolling it into flat flakes and sieving out. This was then sold *to such firms as Vitamins Limited and Glaxo Limited*." (The italics are mine.) In a previous letter (*Medical Press and Circular*, April 29, 1942) Mr. Fairbrother had written: "The extracted germ has been used chiefly as a constituent of infant foods and as part of the diet of invalids. Surely this valuable foodstuff is put to better advantage by building up bonny babies, the man-power of the future, and restoring convalescents to health and strength again than by feeding it indiscriminately to healthy adult people who have no such need for it." A Parliamentary answer to me on Sept. 8, 1942, stated that 99% of the germ thus derived from wheat is allocated to certain favoured makers of patent medicines and foods, some half-dozen in number.

The present Minister of Food (*Hansard*, Nov. 11, 1944) has declared his intention of "gradually" introducing whiter bread, and has explained that he has already in pursuit of this purpose authorized a reduction of home-grown wheat supplied for national bread to 40% instead of 60% previously required. The Statutory Order (March 11, 1942) had exacted this specification: "'National wheatmeal' means, in relation to flour produced after the 22nd day of March, 1942, flour of 85% extraction, *produced in the United Kingdom* [my italics], so as to contain the maximum quantity of wheat germ which, having regard to the type of milling plant, can be included in such flour but so as not to include any coarse bran." This specification was supposed to be operative until reduction of extraction to 82½% was made on Oct. 31, 1944. A further reduction to 80% was made on Jan. 1, 1945.

I submit that the Ministry of Food, which has earned deserved praise for many of its achievements, has unaccountably fallen down in the matter of the national bread. The present subsidy assigned to bread (*Hansard*, March 29, 1945) is £35 million p.a. That subsidy has remained fairly constant in amount throughout the war. It is astonishing and lamentable that our people, paying this enormous exaction, should have been fobbed off until March, 1942, with a national bread which consisted almost wholly of starch. Reversal of that policy in March, 1942, was, I suggest, brought about by action taken in the House of Commons. In December, 1941, I tabled a motion in the following terms:

> "*Wheatmeal Bread*.—That a Select Committee be appointed to inquire what are the considerations which obstruct the exclusive provision as a war measure of a national wheatmeal loaf of the highest practicable extraction, and whether the objections to its adoption are such as to outweigh the practically unanimous recommendations of medical and scientific experts and the value of the tonnage which could be saved by the use of all imported wheat for human consumption, and to report with the least possible delay."

This was supported by over 80 members, including two Fellows of the Royal Society and 9 of the 12 medical M.P.s. In the debate on food (March 3, 1942) I closed my speech with the following statement based upon the motion then upon the Order Paper: "Some time or other an impartial inquiry will have to be conducted into why they [the millers] obstruct what every expert who has approached the matter advises—namely, *the prohibition of the white loaf* and the *provision of a proper wheatmeal loaf*." (The italics are mine.) A week later the Minister of Food in the House of Lords announced the Government's decision to prohibit the milling of white flour (except under very restricted conditions), and to provide a national war loaf made from wheatmeal flour of 85% extraction. It is that loaf which, in the opinion of all the speakers in the House of Lords, has been responsible for the marked improvement in the public health since its enforcement. Reversion to the pre-war white loaf, from which, to secure its whiteness, the germ must be removed, is a thoroughly retrograde step, the reasons for which require explanation.—I am, etc.,

Epsom. E. Graham-Little.

Sir,—As you gave Mr. Graves the extraordinary privilege of printing his letter (March 31, p. 460) it would be well to point out that it is the custom in scientific papers, and in our *Journal* in particular, to publish not only the truth but the *whole* truth. He says: "The raw material from which Bemax is prepared is extracted solely from flour destined for manufacturing purposes." What is the denatured flour made into, and who consumes it?—I am, etc.,

Norwich. Frewen Moor.

The Loaf and Politics

Sir,—It is alleged that 85% extraction flour is a better article of diet than the white loaf for which many of us still yearn. That the use of such flour has saved shipping space during the war and that the bread made from it has supplied deficiencies in our rations are indisputable. But are we to believe that the small amount of vitamin B and other substances present in such flour would really be important to our nutrition in days when a full mixed diet was available? Or is the contention that white flour is, in fact, a deleterious comestible? If these are the views of the advocates of national flour, we, to whom white loaves were a pleasure, should like an explanation of our sound nutritional state in the days when we ate what we liked, and, of course, of that of the French, who possessed so many more varieties of white loaves than our bakers troubled to make.

It is difficult to avoid the conclusion that advocacy of national flour is a political stunt, which, as Prof. J. A. Ryle tells us (March 31, p. 456), "requires State controls and opposes certain interests, and puts the people's health above individual free choice." Now, Sir, advocacy does not require State controls, although advocates may desire them. The function of an advocate in a democratic community is to do all that lies in his power to convince a sufficient number of persons of the correctness and value of his views, which can then be given the force of law, supported by popular opinion. But a self-styled advocate who would force his views on his fellow-men is no better than a Gauleiter, if not, indeed, a Führer.

It is interesting to conjecture why white flour should be singled out for attack when alcoholic drinks and tobacco (which, as everyone knows and admits, can do harm) are immune from professorial censure. Is it supposed that lovers of white bread are less pugnacious than beer barons and tobacco magnates? If I may reply for all those who enjoy these three pleasures, I would say that we have not yet been so cowed by the experts that we will pusillanimously do as we are told. Unless we are convinced that the game of eating white bread isn't worth the candle, the tyranny of forbidding it will lead to the opening of a black market in white bread.—I am, etc.,

London, W.1. A. Piney.

*** Before the war it is doubtful whether more than half the population of this country were getting the "full mixed diet" to which Dr. Piney refers. Bread is the staple food of the poorer classes, and on nutritional grounds it would seem hard to defend a policy which impoverishes such a food. It will be easier to defend when everyone in this country is in fact able to buy a "full mixed diet."—Ed., *B.M.J.*

Ovariotomy or Caesarean Section?

Sir,—In his letter (March 17, p. 383) Mr. Eardley Holland advocates the removal of the ovarian cyst followed by vaginal delivery in the case of a patient already in labour. He states that "if the cervix is not fully dilated labour must be allowed to continue until it is and then the child delivered. The presence of a recent abdominal wound does not interfere with natural labour; pain is relieved by morphia." On page 311 of the 8th edition of Eden and Holland it is stated that "the foetal respiratory centre is extremely sensitive to the action of morphia and it should on no account be given if delivery is expected to occur within the space of 3 hours because of the risk of foetal apnoea ; many foetuses have failed to survive birth because this important rule has not been observed." Hence it appears that the unfortunate woman is left with a 14-inch abdominal wound plus the pains of labour for the last 3 hours of the first stage. The fact that continuous caudal anaesthesia has been so extensively used as an analgesic shows that morphine in ordinary doses is unsatisfactory to overcome the pains of the first-stage contractions even without the added pain of a large abdominal incision.

The 7th edition of *Midwifery by Ten Teachers* states that in a case seen early in the first stage it may not be advisable to wait, "in which case the operation must be proceeded with at once and the delivery of the child effected by Caesarean section. An alternative is to suture the abdominal wound and allow labour to proceed naturally. Of the two procedures the first is the more merciful and has the further advantage of not submitting the abdominal wound to strain."

It may be noted that Mr. Holland calls on the support of the dictum of the late Dr. Herbert Spencer, who never did a lower-segment Caesarean section in his life and whose views are not necessarily applicable in 1945. The question arises whether Prof. S. J. Cameron, Mr. Holland, or Mr. Stanley Way remain with their patients after ovariotomy and wait to deal with their pain personally, or whether they leave a house-surgeon to cope with the vaginal delivery of a patient who has a large laparotomy wound to strain on as well as the pains of labour. Perhaps one is also permitted to wonder if any one of them has ever had a large incision in his own abdomen, although it is too much to hope that they also had the added pains of labour which they urge should be suffered by women. Prof. Stander, on page 986 of his 8th edition of *Williams' Obstetrics*, concludes: "We are of the opinion that the double operation is preferable, believing that a woman should not be subjected to the strain of labour immediately following an abdominal operation."

If an operation is performed before the cervix is fully dilated an incision from the pubes to the umbilicus, a lower-segment Caesarean section, and then the removal of the cyst is the treatment which most women would choose who know the facts. This treatment would make them inclined to cater for further pregnancies.—I am, etc.,

London, W.1. CLIFFORD WHITE.

SIR,—The letters on this subject, as well as those on placenta praevia, show that opinions still differ as to the most suitable methods of surgical treatment. From past experience I cannot regard the presence of Caesarean scars as lightly as Mr. C. McI. Marshall (March 24, p. 421) or my friend Victor Bonney (March 31, p. 459), for it has been my lot to operate on several cases of rupture through the scar. The possibility of this complication has been in my mind ever since I saw a young mother lying dead on the slab of the admission room through rupture of the uterine wound. From my experience of this complication I consider that the prognosis is influenced greatly by two circumstances. It is less serious if the contents of the uterus are extruded completely into the peritoneal cavity, as the uterus can then retract effectively. On the other hand, if there be only partial escape of the child through the rent while there is incomplete separation of the placenta, death may ensue rapidly from haemorrhage and shock. The bleeding is not so copious if the uterine wound is avascular with the placenta situated at some distance from it. Danger may follow from quite a small rent, for, in one case I operated on, the child was stillborn while the patient nearly lost her life from the formation of a tear which was not much longer than one inch ; the placenta lay immediately beneath the scar.

Mr. Marshall wisely emphasizes the great importance of a suitable anaesthetic in cases of placenta praevia, where the patient's condition is critical. With advantage the choice may be limited to three: intravenous pentothal, local analgesia, and cyclopropane. The only objection which might be lodged against local analgesia in desperate cases where bleeding is continuing is that it adds slightly to the length of time of the operation.

Mr. Marshall and I are in complete agreement as to the management of placenta praevia, with the exception that he invariably prefers the lower-segment operation. Although his experience of this method of treatment in these cases is gratifying, I believe that, for those who only occasionally perform Caesarean section, the classical operation is the one which should be chosen. On the occasions when I performed it for placenta praevia, I always felt that I was entering a dangerous territory owing to the increased vascularity in this area of the uterus. So I abandoned it when my former colleague, Dr. J. Hewitt, whose surgical skill and judgment I admire, informed me that he no longer performed the lower-segment operation in cases of placenta, as he was convinced that with exsanguinated patients the chance of recovery was lessened in those instances where profuse bleeding occurred during difficult removal of the placenta. Mr. Carnac Rivett has also written to me stating that he invariably chooses the upper-segment operation in dealing with this abnormality of pregnancy ; at the same time he always uses pentothal, administered by the drip method, as an anaesthetic.—I am, etc.,

County Maternity Hospital, Bellshill. S. J. CAMERON.

Repair of the Oblique Hernia

SIR,—Mr. James F. Riley's letter on this topic (March 17, p. 386) and his reference to "the use of strips of hernial sac as fascial sutures" prompt me to record that this procedure is also applicable in other kinds of external hernia. In many large ventral hernias—umbilical and incisional—strips of adequate length and strength can be cut from the sac and used to complete the necessary repair. In femoral and direct inguinal varieties the sac does not provide sufficient material, but the same method of repair can be used if one takes strips cut from the sac of an inguinal hernia previously removed from another patient. As Riley writes: "The length and strength of the material which can be obtained from such a source are quite remarkable." Recently I operated on a man with a very large scrotal hernia. After his hernia had been repaired by the method described there was enough excellent material left over for the repair of at least half a dozen other cases. In this particular case 1/2-inch-wide strips of the sac had a breaking strain of fifteen pounds. In thick sacs 1/4-inch-wide strips are generally used ; where the sac is thin wider strips are cut. Any with a breaking strain of less than five pounds are discarded. By arranging an operating session devoted to hernias requiring the "hammer" method of repair, and by heading the list with two large oblique hernias, it is possible to obtain enough suitable strips for the repair of, say, five or six cases.

No claim is made that this method of utilizing the sac gives better results than other repair procedures. Satisfactory results depend not so much on the particular method adopted, but rather on the manner in which it is applied. At the same time my method has certain advantages over fascia lata strips: it is economical in time and material, and avoids the infliction of a thigh wound which may provide patients with grounds for complaints—real or imaginary. Mair (*Brit. J. Surg.*, 1945, **32**, 381) states that in his experience pain, which may be quite intractable, occurs in 25% of subjects.

In an enumeration of the "disadvantages of fascia" Mair writes: "The needle used for the Gallie method is large, and apt to traumatize the inguinal ligament. There is also a risk of penetrating the femoral vein. This complication has been frequently mentioned in the literature . . . and in one example which came to my notice death resulted on the operating table." Can such a disaster be fairly described as a "complication" of the Gallie method? Most competent surgeons would be inclined to use a stronger and more appropriate term.—I am, etc.,

Dundee. F. R. BROWN.

Recurrent Dislocation of the Ankle

SIR,—I was interested in Mr. E. Hambly's note on recurrent dislocation of the ankle (March 24, p. 413). The condition described is one more accurately referred to by Elmslie (*Ann. Surg.*, 1934, **100**, 364) as a recurrent subluxation of the ankle-joint. Undoubtedly the initial injury is of some severity, but the history of the original severe sprain is not so frequently elicited. While in a number of cases, particularly those with superimposed recent sprains, the clinical impression of increased inversion is not apparent, few would agree with the generalization that "further examination of the ankle does not elicit any more inversion than is found in a normally sprained ankle without a ruptured external ligament." If the case falls within the second category described—namely, that in which the presenting symptom is a "feeling of weakness" or a recurrent "giving way."—attempted inversion will rarely be accompanied by any peroneal spasm, and will not require local analgesia, More often, however, as Mr. Hambly points out, the patient presents himself as the result of a recent sprain, and peroneal spasm is usually related to the degree of pain experienced. The intravenous injection of 0.5 g. of pentothal sodium, given with the patient on the x-ray table, secures rapid and adequate relaxation, and allows the ankles to be compared both clinically and radiologically under similar conditions.

That the only treatment for an ankle with a rupture of the external lateral ligament is operation is indeed a bold statement, but I feel that Mr. Hambly refers to the old case with recurrent symptoms; even so, the treatment should always be guided by a proper assessment of the symptoms, and the simple measure of raising the outer border of the heel will often obviate any operative procedure.

Any operation devised to prevent a recurrent subluxation of the talus must provide for a reconstruction of the anterior talo-fibular ligament, and such a reconstructed ligament must not vary in length. The operation described is both simple and ingenious, but fails to fulfil either of the criteria mentioned. The calcaneo-fibular ligament is admirably reconstructed, but the anterior portion of the split peroneus longus tendon has but one fixed attachment—namely, that at its fibular extremity—and bears no functional resemblance to the anterior talo-fibular ligament.—I am, etc.,

Kirkham, Lancs. J. ROWLAND HUGHES, M.B., CH.B.

SIR,—I feel that Mr. E. Hambly's memorandum under the above heading (March 24, p. 413) should not pass unchallenged, advocating as it does a needless operation. By "dislocation of the ankle" he appears to mean rupture of the external lateral ligament—hardly the same thing! Apart from a wide experience of injuries in others, I have personally sustained a sprain of the ankle with an audible rupture of the external ligament, and also a genuine dislocation. The foot was so inverted that I could see the sole as I lay on the ground, and the deformity was reduced by replacing the astragalus in its socket. There was, fortunately, no fracture. There was, of course, much pain and swelling, but after a week's rest and some massage I started gentle walking in about a week, and was playing tennis a month later. Such exercise naturally was followed by swelling, but as it subsided during the night no harm was done and my ankles are as good as ever they were.

I feel that if modern young orthopaedic surgeons realized the value of early and persistent active movement, operations would be avoided, and patients discharged much earlier and with better results than are often seen to-day.—I am, etc.,

Bearsden. C. M. FINNY.

Problems of Cortical Hyperadrenalism

SIR,—Dr. F. Parkes Weber's letter (March 17, p. 384) on problems of cortical hyperadrenalism is of great interest also from the point of view of the study of the aetiology and pathogenesis of malignant tumours. The group of hormone-producing tumours (ovary, testis, chorion epithelioma, pituitary, parathyroid, etc.) have aroused much interest in recent years, not only because of their peculiarities but also because they allow a closer scrutiny of the interwoven endocrine function and neoplastic proliferation.

The variations of the primary or secondary sex characters resulting from the impact of the endocrine environmental factors on the genetic sex-determining factors can perhaps be considered as the half-way house on the road leading to neoplastic degeneration. An example is the so-called masculinizing tumours of the ovary, which may be either the arrhenoblastoma or the granulosa-cell carcinoma. The latter is more frequently a feminizing tumour.

The explanations given by Dr. Parkes Weber are, to say the least, very thought-stimulating. Although several different hormones have been isolated from the adrenal gland, the conception of a distinct androgenic zone in the adrenal cortex, liable to undergo hyperplasia or to function at a lesser rate than normal, is not easily acceptable. Halban's views (1925)[1] that the cortical hormone is not a specific male activator but may exercise an influence on either gonad are worth recalling. According to Halban, when a female shows masculinizing effects she does so because at birth she was a potential hermaphrodite, and the effect is caused by the stimulation of male gonadal rests in the ovary. That holds to-day, notwithstanding the facts brought to light as regards the sex-determining factors in the chromosomal pattern. It must also be borne in mind that in the arrhenoblastoma the tumour may be the effect rather than the cause of the increase of the androgenic hormone in circulation. Moreover both masculinizing effects and increase of androgens are not the rule with these tumours.

The question whether "the mild forms of feminism producing cortical hyperadrenalism in females, probably without any actual cortical endocrine tumour, could account for some cases of excessive development of the uterus with early and excessive menstruation and myomata and possibly exaggeration of breast development and secondary sex characters" can be answered in the positive in a hypothetical way. The importance, however, lies in the problem whether these symptoms and signs are not analogues of pre-malignant conditions in other spheres of oncology.

As regards the active thymic tumour or delayed involution of a large thymus, giving rise to either macrogenitosomia or gynaecomastia with hypogenitalism (referred to by Dr. Parkes Weber) due to a virilism-producing thymic hormone in the former case and a feminizing thymic hormone in the latter, it must be emphasized that although a degree of antagonistic relationship between thymus and gonads exists, it seems not to be of simple reciprocal nature. The influence of the thymus on the development of young animals and osteogenesis and normal joint formation was known long ago. That in spayed rats the thymus does not undergo involution, or that testosterone propionate injections affect profoundly the thymus, does not mean that this gland affects the gonads in the reverse directly. Heavy doses of x rays delivered to the thymus of newborn rats resulting in the destruction of this organ (Jolles, 1941)[2] do not produce any effect on the testis.—I am, etc.,

Shall We Nationalize Medicine?

SIR,—The issue of a 100% service surely revolves on how much we value freedom. I am impelled to raise my voice not only by Lord Horder's challenge in his Cardiff address (March 17, p. 357), but also by Prof. J. A. Ryle's academic reply (March 31, p. 456). My claim to speak rests, not like theirs on eminence, but on a fairly wide experience. I have climbed over the fence and tried the grass in the next field several times. Those I have sampled include six existing services, a number of general practices, several voluntary hospitals, and also teaching and research in universities. I have learned to value certain freedoms, and here are some which I hold to be at stake.

I value the right to stand for political election like any other citizen. A Government officer is normally debarred from candidature while holding office, but is free to resign and earn a private living and then put up for election. Prof. Ryle argues for an increase in correct political activity by the profession and at the same time wants to make us all 100% officers of the State. Would this not quite properly debar us all from candidature except at the price of retiring from earning a living? How does he reconcile his apparently conflicting advice?

Prof. Ryle says: "First of all it is an assumption that State medicine must necessarily impose controls on the professional thought and actions of a doctor and spoil his age-long human relationships with his patients." I will agree that any estimate of the future is an assumption, but since experience is the only basis for prognosis, and all the evidence of my experience shows that these very things are happening in the Services now, I ask, What evidence does he offer to suggest that a new service might make any effort to avoid the grave faults of the present?

To me the most striking common factor in services is the whittling away of many professional freedoms, which all add up to a big debit. Consider the tuberculous patient. Possibly a poor case for freedom, but he still has a trace; up to the point of public danger he may refuse treatment, but the price has gone up recently. In the official "Model Leaflet: Allowances and Grants" we read: "These allowances will be paid . . . *provided* that he follows a course of treatment advised by the tuberculosis officer of the local authority" (my italics). Is this a "model" of things to come? Together with the patient's waning right of free choice goes the doctor's right to retire from a case. Another freedom that I value is the right to prescribe as I think best. This has never been strong in services, and under wartime drug restrictions it is in danger of vanishing.

Another freedom that is ebbing is the freedom to give one's personal best to each patient. I regard this as crucial. I have met service administrators who exert direct pressure, although insidiously because they will not put it in writing, to scamp the work and speed the flow of human cattle through their clinics. When I challenge I am told that "the mass method is the only way," or that "there is a shortage of doctors," but in any case "it is an order." I have tasted this in every service pudding I have eaten. Like the flavour of weevils it cannot be disguised by any amount of jam. The point is that we have not yet seen a service that sets out to put the interests of the individual patient first. I have always thought and taught that this is the first thing in therapeutics—the foundation stone that is still solid after 2,500 years. The mass method of approach is satisfactory for animal work, and most laboratory workers recognize that it cannot be directly or completely applied to man because man is something more than animal. That its attempted imposition on man is unsatisfying to patient and doctor alike I have no shadow of doubt.

The freedom to set up experiments to test a theory is one that I value too, including man within voluntary and human limits, and experiment by definition includes control for measurement. Prof. Ryle states his belief in his theory but admits "until we have tried it neither Lord Horder's assumption nor mine can be proved the more correct." Therefore I assume that he considers the 100% service plan to be in the nature of an experiment. But where is his control? What is left from 100% for any kind of comparison under equivalent conditions? Does he accept Lord Kelvin's definition that "science is measurement"? If so, he has thrown away his yardstick. I can picture plenty of political control in a 100% service, but because it rules out scientific control from the start I submit that it is not an experiment and therefore could never prove anything. The only comparisons left would be the results on the health of the next generation to set against that of the present and of the past, which would contain so many enormously variable factors as to be scientifically fantastic and totally invalid.

Finally, to be constructive, let me welcome discussion and plan. Let us collaborate and organize to improve by all means. Let us indeed try a unified national service. But I press that this is too big either to be measured by the yardstick of science or "bossed" by the big stick of politics. By what, then, could it be controlled? I suggest that it could be balanced by a principle, and the only one that is big enough is freedom. If I am right, this means that we must not agree to a 100% service under any circumstances. The only prescription that is likely to prevent the monster medical machine from becoming a myxoedematous monstrosity is adequate dosage with freedom; to be available at all times, and at every stage: freedom for the patient to seek private aid without penalty, provided only that in certain cases he does, in fact, take some specialist advice; freedom for the doctor to work in the service or get out and earn a reasonable living at his profession on his own, responsible, as of old, only to his patients, subject only to his conscience and his King.

Would this not put the service on its mettle and the private profession too? Let them vie with each other to serve the nation in friendly rivalry, and I think both will live and flourish healthily. But if it so happens that England lets this freedom go, either by default under hasty wartime legislation or by direct vote after due time for consideration, then I for one will reckon it to be the greatest disaster in the history of medicine. I will then pack my traps and sadly restart my travels in pursuit of freedom, even, as Sir Walter Langdon-Brown has suggested (*Daily Telegraph*, July 28, 1944), as far as the wilderness.—I am, etc.,

Lee-on-the-Solent. J. W. DE W. G. THORNTON.

SIR,—Lord Horder (March 17, p. 357) postulates a number of axiomatic truths that no one will question. At the same time this eminent authority gives expression to some strong protestations of a controversial nature. For example, the sponsors of the White Paper are arraigned as accessories in a course that must ultimately lead, so it is contended, to "regimentation and control by the State." The evidence adduced in support of this indictment hardly rises above the level of the hypothetical. It is noteworthy that no recognition is made of those doctors who have indicated their reactions to the White Paper as favourable (Q. 30 of Questionary) or have plainly signified their approval of a "salaried remuneration or some similar alternative which will not involve mutual competition" (Q. 17 and Q. 18 of Questionary). Is it considered that they are lacking in "good brains and healthy ambition" simply because they are not attracted by the adventures—and the hazards—of competitive private practice?

The health centre, according to Lord Horder's conception, takes the shape of a hospital out-patient department where the Ministry pays for the services of the specialists. That is very different from the health centre of the White Paper, which is designed for a "group" of general practitioners working together. And now that some public health authorities have laid claim to the same label for their clinics, the appellation "health centre" does not make for clarity. It seems high time to discard the term in reference to "grouped" general practice, for which "consulting centre" might be better.

I would beg leave to deprecate the emphasis on the sentiment that "we"—the medical profession—"stand for sane knowledge, selflessness, and mercy in a world gone mad." That is a high standard, but is it not a little unsympathetic to the rest of the population? Why "a world gone mad"?—I am, etc.,

St. Annes-on-Sea. JOSEPH PARNESS.

SIR,—The last paragraph of Prof. Ryle's letter states by far the most important point in the controversy. He says: "*Until we have tried it* neither Lord Horder's assumption nor mine can be proved the more correct" (my italics). Let there be no misunderstanding: once medicine is nationalized there would be no return from the disaster, both to the community in general and to the medical profession, which many of us believe it would bring about. It would be impossible to say: "We find this experiment a failure; let us go back to the *status quo*."

The Church of England is a very good example of political control. The bishops are, I believe, appointed on the recommendation of the particular political party which is in office at the time of a vacancy. In my view, the chaotic condition of the Church to-day is due largely to the unfortunate practice of many of the bishops, who seem to mistake theology for politics. So it would surely be if our profession were nationalized. May it never happen.—I am, etc.,

Birmingham. ERIC W. ASSINDER.

SIR,—Prof. J. A. Ryle (March 31, p. 456) aims high if his media Utopia is to contain administrators who will not interfere with clinicians. He leaves out of account human frailties, not the least of which in the "administrator type" is the "itch" to interfere beyond their zone of usefulness.

I was once called upon during my Army service to give an explanation of my treatment of a case of fractured femur by a splint other than a Thomas splint. My first explanation—an oral one—that I had been offered a Thomas splint and refused to use it was not accepted, and I was asked to put the matter in writing. My written explanation was accepted, but I received a cautionary note to the effect that the Thomas splint had been manufactured in large quantities for the Army for treatment of this type of injury, that I knew the usual channels of procedure when a departure from Army technique was involved, and in future I was to use those channels. The time-lag would, of course, have been unpleasant for my patients and irksome to me, so from that date the usual Army technique was adhered to.

I bring forward this point to illustrate a possible (to be more honest, a certain) snag in State-administered medicine. In case any of your readers should think I spent my Service life kicking against the goad, I would like to add that that was not so. I enjoyed every minute of my Army life, had quick promotion with no previous experience, and was on excellent terms with all my senior officers. On the other hand, I always regarded my conditions of service as a voluntary surrender of individual liberties for the good of a cause, the ultimate aim being the restoration of those liberties to all serving officers for (we foolishly thought) all time.—I am, etc.,

Birmingham. L. H. G. MOORE, Major, R.A.M.C. (ret.).

SIR,—May I, as a very junior member of the profession, say how much I agree with Prof. Ryle's arguments in favour of a national medical service? In the post-war era, when each of us will have to do his utmost to help to restore the country to normal, it is difficult to see how we doctors can remain aloof from schemes of reconstruction. Unfortunately, up to the present, the proposed State medical service seems to have concerned itself almost entirely with the benefits which are to accrue to the public, with the result that most of us have formed the impression that we are to have more work, more "control," and a limited remuneration. Until this impression is finally cleared from our minds I fear that little progress will be made.

It will, I think, be conceded that if all members of the community were brought into the N.H.I. scheme and the doctors' terms of service were left unchanged—viz., a 24-hour day and a 365-day year—an impossible situation would arise. Few doctors would survive such a life for ten years, and new recruits for the profession would be rare indeed. The obvious solution to the problem, and one which in my opinion has been long overdue, is to arrange for regular working hours—say, from 9 a.m. until 6 p.m.—with a rota of doctors to stand by for emergencies during the remaining part of the day. It is true that such an arrangement would mean that a patient might be attended by several doctors during the course of an illness, but I believe that the public would show little opposition to such an occurrence. The beloved and indispensable family doctor is rapidly dying a natural death in more senses than one, and it is doubtful if he will ever be replaced. I, for one, do not believe that it is necessary to become a personal friend of my patient in order that I may do him the maximum amount of good.

We talk a great deal about our "freedom" at present, but surely we are free in theory only. The British doctor of to-day is tied to his practice and his patients just as firmly as was the negro slave to his plantation and master before the Emancipation Proclamation of 1863. In no other profession would such conditions be tolerated, and yet many of us are actually fighting to prolong our slavery. There are men who profess to be ready and willing to give their services at any hour of the day and night to any type of case. In seven years of practice I have not met such a man, and I am not ashamed to say that I consider nine hours' routine work each day to be quite sufficient, both in my own interests and in those of my patients.

A last (but not least) word on behalf of our wives. Is it not high time that the surgery premises, with their dreadful tyranny of telephone and door-bell, were dissociated from the doctor's private residence? Let us not forget also the hardships caused by the initial purchase of a practice and the anxieties of personal illness and provision for retirement. Over and above all the disadvantages of a State medical service, it is plain that there exists a golden opportunity for the betterment of our lives. This is our great chance, and if we seize it with both hands I venture to suggest that future generations will look back with surprise and incredulity upon the conditions which their fathers tolerated and even fought to retain.—I am, etc.,

Blackpool. H. DAKIN, M.B., CH.B.

Nursing and Tuberculosis

SIR,—For several months the views of authoritative writers have appeared in your columns concerning the degree of risk to young nurses when exposed to infection from tuberculous patients. The weight of expert but apparently divergent opinion leaves the mind of the simple observer still a little confused, but the letter of Miss Evelyn Pearce (March 24, p. 424) helps by reminding us that we are dealing with a problem that calls for urgent and radical treatment based, not on clinical laboratory findings, but rather on humanitarian principles.

So long as Dr. W. E. Snell writes primarily as a physician and Drs. P. W. Edwards and A. C. Penman as hospital administrators, the battle of the giants will continue, but, as a general practitioner, I would like to support the argument of Miss Pearce, who, with a wealth of experience behind her, believes that the conditions under which the student nurse toils "as a hewer of wood and drawer of water" are a menace to her health and a grave reflection on our hospital system. This letter is inspired by a disastrous case of hospital "slavery" which recently came to my notice.

In late 1943 a healthy girl, whom I knew as a panel patient, started her training as a student nurse at a general hospital and had in her care several tuberculous patients. On Oct. 13, 1944, she came to see me saying that she felt "very ill indeed." After examining her I gave her a note for her medical superintendent, stating that she was feverish, had lost weight, and, in my opinion, was urgently ill. She was *x*-rayed three days later and the medical superintendent kindly sent me the report, which read: "Marked opacity in right lower lobe area suggests that there has been recent consolidation there, probably now resolving." Although at this time she was running an evening temperature of 100–101°, she was kept on duty *for a further four days* before being warded. The sputum being positive, her subsequent progress to a sanatorium brought her under the care of Drs. Edwards and Penman, who have treated her case with an energy which suggests that their reputation has not been built solely on administrative ability.

This student nurse trained in a general hospital which justly had a high reputation for careful work and progressive treatment and the nurses are usually well looked after. Nevertheless it appears to be a serious fault in our great hospitals that the young nurses are regarded as cogs in the machine rather than as human beings. Until this very serious fault is remedied there will inevitably be reluctance on the part of thinking parents to encourage their own daughters to enter a profession which might otherwise attract.—I am, etc.,

Urmston. REGINALD H. TOOTILL.

Identification of Gas Cylinders

SIR,—In your issue of March 17 (p. 381) I note the sad fatality due to faulty identification of cylinders. In common with most anaesthetists I deplore the lack of standardization; there should be universal cylinder markings of an indelible kind and obvious colour and foolproof fittings in all gas-type machines.

Apart altogether from the need for a full personal inspection and testing of the apparatus and a routine "once-over" inspection before each administration, may I suggest the following additional safeguards: (1) All cylinders should have fitted some audible warning giving ample notice of "running out." (2) Foolproof connector to all tubes from cylinders to flowmeters. The Coxeter-Mushin apparatus has fitted an excellent type of clip known as the "Romac clip," as used on compressed-air machines. These are calibrated in three separate sizes, making a special size for each cylinder and its junction to its individual flowmeter. For example, it would be impossible, say, to connect the NO_2 or the CO_2 cylinder to the oxygen flowmeter as it would not fit and simply "blow off."—I am, etc.,

London, N.8. A. OWEN-FLOOD.

Organization of Research

SIR,—Prof. A. V. Hill is stated in the *Journal* of March 17 (p. 374) to want a central organization for scientific research under a Minister. Does he really think that such a thing will help all independent thinkers to put forward new ideas for research? By centralizing all research work Prof. Hill would have every worker submit his proposed work to an official without any guarantee that it will not be filched. Filching does exist in all kinds of intellectual work whenever the chance occurs, and unless Prof. Hill can guarantee security, the less he pushes his idea the better.—I am, etc.,

Swansea. G. ARBOUR STEPHENS.

Obituary

A. W. SHEEN, C.B.E., M.S., F.R.C.S.

We regret to announce that Col. A. W. Sheen, Provost of the Welsh National School of Medicine and for fourteen years professor of surgery there, died at the Cardiff Royal Infirmary on March 28. He had represented the University of Wales on the General Medical Council since 1928.

A colleague writes:

Alfred William Sheen was the son of a well-known Cardiff practitioner who was also a surgeon to the Royal Infirmary in the pre-consultant days when the hospital was staffed by general practitioners. He was born in 1869 and educated at University College, Cardiff, and Guy's Hospital, where he was a distinguished student, and qualified in 1892, taking honours in the M.B., B.S. of London University, and then proceeded after the usual resident appointments to the M.D. and M.S. degrees and the F.R.C.S. He returned to Cardiff and was appointed assistant surgeon to the Infirmary and confined himself to consulting practice. Lynn Thomas (later Sir John Lynn-Thomas) and Sheen were the first to restrict themselves to consulting practice in South Wales. In the South African War Sheen served as surgeon to the Imperial Yeomanry Field Hospital throughout the campaign and was mentioned in dispatches. A younger brother was in the Royal Navy and landed with the Naval Brigade for the defence of Ladysmith, and was an engineer captain in the Battle Cruiser Force 1914–18; he later attained the rank of rear-admiral. Sheen would undoubtedly have achieved equivalent high rank had he decided to remain in the Army, for which perhaps he was best fitted. He resumed practice in Cardiff and now became full surgeon to the Infirmary at an early age.

In the first world war Sheen formed and commanded the Welsh Hospital at Netley, which was afterwards established in India as the 34th (Welsh) General Hospital, where he remained until 1919, and during the later period was consultant surgeon to the war hospitals in India. For his services he was made C.B.E. in 1918. He had now been away from home for five years, and on his return found it difficult to regain his former position as his term of appointment to the Infirmary had now expired. Sheen was elected under an old rule of retirement at the age of 60 or after 20 years on the full staff, and the latter ruling applied in his case when he was just over 50 and the Infirmary was deprived of his services at the best time of his life. Fortunately the Welsh National School of Medicine was completed in 1921 and Sheen became its first professor of surgery and director of the surgical unit, where his administrative ability in the inauguration of the School was invaluable. He was an excellent teacher and proved to be a successful full-time professor. He became Provost of the School after relinquishing his professorial duties to his chief assistant, Lambert Rogers, but on the outbreak of the present war when Prof. Rogers was mobilized in the R.N.V.R. Sheen was again recalled to direct the unit and voluntarily carried out these onerous and double duties to the time of his death.

He was County Director of Voluntary Aid in Glamorgan, and here his military and surgical experience were indispensable in a vast industrial area like South Wales. In this work he was greatly assisted by his wife, and they took a leading part in the social life of the county generally. At Senghenydd, the scene of our worst mining disaster, Sheen was one of the first to reach the pit-head and immediately took charge of the rescue operations. He was a born leader of men in such an emergency and all instinctively turned to him for instructions. The writer was immediately ordered to select the rescue parties, and a long queue of young miners, stripped to the waist, passed in turn for examination. I shall always remember his warm appreciation of the natural courage of the miner and the characteristic squaring of his broad shoulders on reporting, "All correct, Sir. There was scarcely a fast pulse amongst them." He replied, "They are brave fellows," and then addressed them personally. The next task was to convert a hall into a temporary hospital, which was quickly done under his capable supervision.

Sheen was past-president of the Hunterian Society and president of the Section of Surgery at the Annual Meeting of the B.M.A. in Cardiff in 1928, and contributed regularly to the medical journals in his younger days. The end was characteristic of his indomitable spirit. He had trudged three miles through the heaviest snowfall on record locally to keep an appointment at the medical school office. This effort at his advanced age was too much even for the tough fibre of his robust and well-preserved constitution. Acute heart strain resulted and was fatal in a little over a month. He died at the Royal Infirmary which he had so loyally served for almost half a century.

Prof. R. M. F. PICKEN writes:

Others can speak better of the distinguished part played by Col. A. W. Sheen in the development of the Welsh National School of Medicine during its difficult childhood, but it may be appropriate that one whose contacts with him became close only in his maturity should pay a tribute to his memory. When I was concerned primarily with local government the project of the Guardians to build a new hospital became a public issue which affected the Corporation and the Medical School, and Sheen became an active member of a medical committee set up by the Guardians to advise them on planning and other technical matters. His views were broad and idealistic and had much influence on the moulding of what is now one of the finest municipal hospitals in the country. He was a firm advocate of close association between the medical school and this and other municipal institutions, and constantly directed his influence toward furthering this object. He was instrumental in securing joint appointments as between the school, the voluntary hospital, and the municipality as a means of attracting young specialists into the area, much to the advantage of all parties.

Sheen's ideas for remedying the defects of medical organization were radical. He expressed himself in speech and writing with vigour and clarity and without compromise, but he met opposition with equanimity and without rancour. Age did not stale the adventurous character of his mind. In administration he rode with a light rein and kept effective contact with his colleagues. He constantly stressed the importance of research among the functions of the medical school, but he took an expansive view of its teaching duties not only for medical students and graduates but also for ancillary workers in health. His personal relations with his colleagues were friendly and intimate, and they will cherish the memory of his many acts of personal kindness.

Surg. Capt. LAMBERT ROGERS, R.N.V.R., professor of surgery, University of Wales, cables from over-seas:

I am deeply grieved to hear of the death of my friend and colleague Prof. A. W. Sheen, whose kindness I can never forget. So much in the development of medical education in Wales was due to his far-reaching views and energetic drive that the University and Medical School and the Cardiff Royal Infirmary have sustained a grievous loss. "The Colonel," as he was fondly called by his friends, was always young in outlook and his ambitions were always for all that is best is surgery and in medical education generally. The son of a distinguished Cardiff practitioner, he had been Arthur Durham's house-surgeon at Guy's, and early in his surgical career was one of a small group of surgeons to ligature successfully the innominate artery. Having had a distinguished Army career in the last war he would have loved a Service appointment in this, but being over age for such he worked harder than ever for the medical school in which he was both the first professor of surgery and the first provost. He retired from the chair of surgery in 1935, but remained on as administrative head of the school, and after the death of Mrs. Sheen early in the war returned to the chair to enable his younger colleague to go on active service. He published numerous and valuable papers on surgical subjects, was a sound surgeon of wide experience, an excellent teacher and speaker, and an able administrator. He had a great gift for encouraging younger men, was very much beloved by his friends and students, and will be sadly missed.

HAAKON SAETHRE, M.D.

On Feb. 9, 1945, several Norwegian patriots were arrested as hostages and sentenced to death by a German summary court-martial. They were immediately afterwards shot as a reprisal for the killing the day before of the Quisling police chief by the Norwegian Home Forces. Among the Norwegians executed was Dr. Haakon Saethre, chief medical officer of the psychiatric department of Oslo City Hospital, and one of the most prominent Norwegian neurologists and psychiatrists. His death as a hostage reflects dismally the terrorism practised by the Germans in occupied Norway.

Haakon Saethre was born in Bergen in 1891, and had his post-graduate neurological and psychiatric training at the State Hospital in Oslo and at the State Psychiatric Clinic. He became head of the psychiatric department of Oslo City Hospital in 1933, and through his excellent clinical work and outstanding abilities as an administrator made his clinic one of the most inspiring psychiatric institutions in Norway. Dr. Saethre's scientific work covered a large field of neurology and psychiatry. His works on oxycephaly, disseminated sclerosis, general paresis, and other topics are already classical neurological literature. A number of articles on various subjects are to be found in the Scandinavian medical journals. During the last 10 years he made extensive studies of chronic alcoholism, and of the neurological and psychiatric sequels of head injuries. He was official Norwegian delegate to several international congresses, and was president of the Inter-Scandinavian Congress of Psychiatry in Oslo, 1938. As medical consultant for Oslo City Child Welfare

Committee since 1933, he soon realized the need for specially equipped psychiatric departments for children, and the war only had postponed the realization of his plans regarding this important preventive field of medicine. As honorary president of the Norwegian Society of Mental Hygiene for several years, Dr. Saethre also devoted much of his unusual energy to popularizing the general principles of mental hygiene. He was a very active member of the Norwegian Neurological and Psychiatric Societies.

Besides his many official duties, Dr. Saethre also had a large private practice in Oslo, acting chiefly as a consultant, and he obtained the confidence and admiration of a vast number of patients from all parts of Norway. His interest in clinical work was intimately combined with profound personal and social care for the sick individual. Dr. Saethre's assistants will always remember his extraordinary knowledge and his ability to convey this knowledge to his staff.

DENIS JOSEPH COFFEY, LL.D., M.B.

We regret to announce the death, on April 3 in a Dublin nursing home, of Dr. Denis Coffey, late President of University College, Dublin, and Vice-Chancellor of the National University of Ireland, who for 25 years represented that University on the General Medical Council.

Denis Joseph Coffey graduated B.A. with first-class honours in 1886 and M.B., B.Ch. in 1888 at the old Royal University of Ireland, of which he was later elected a Fellow, and went for postgraduate study to Louvain, Madrid, and Leipzig. He became professor of physiology, and later dean of the Faculty of Medicine, in his own University and lecturer in biology at St. Patrick's College, Maynooth. He served on the Royal Commission on Trinity College and the University of Dublin in 1906, and was one of the Dublin Commissioners under the Irish Universities Act, 1908, in which year he was elected President of the newly created University College, Dublin. Trinity College conferred on him the honorary degree of LL.D., and the Royal College of Physicians of Ireland its honorary Fellowship. He was appointed to represent the National University of Ireland on the G.M.C. in 1920, and seven years later became President of the Free State Medical Council.

At the time of his retirement from the presidency of the N.U.I. in 1940 a tribute in the *Journal of the Irish Free State Medical Union* recorded that to the young University Dr. Coffey gave all his energies unselfishly and without reserve, assuming the whole burden of its early administration. As the University grew he did not spare himself, and long after he might have safely delegated power he did not do so because he was impelled by a whole-hearted conception of duty. The successful growth and assured standing of the Medical Faculty were due in part to his wisdom and to the character he gave to its formation.

The death on March 26 at Brentwood, Essex, of Dr. **ARTHUR QUENNELL**, aged 78, removes not merely the doyen but the respected and acknowledged standard-bearer of the medical profession in that neighbourhood. The son, grandson, and great-grandson of medical men in Brentwood, he was the head of a large firm which includes also his nephew, Dr. William Quennell, representing the fifth generation in continuity. He had witnessed the development of a small country market town into an affluent residential suburb of London, where his services were equally acceptable to the Essex farmers and the more sophisticated immigrants of the last forty years. He was of the very best type of general practitioner, and took immense pains to keep fully abreast of progress in all branches of medicine. It was common knowledge, too, that he maintained an unvarying high standard of professional ethics and rectitude. Not only was he a supporter over many years of both the leading medical charities, but his private liberality was inexhaustible: it was no uncommon thing for him to summon a consultant from London for some urgent case and himself to pay the fee if he knew it would overstrain the patient's resources. His medical education was obtained at St. Bartholomew's Hospital, whence he qualified as M.R.C.S., L.R.C.P. in 1892. Thereafter he was house-surgeon and house-physician at the Royal Free Hospital, and resident medical officer at the Evelina Hospital for Children. Until laid low by serious illness about a year ago, he had remained in harness, no doubt partly or wholly through determination to do his share in the country's war effort. Dr. Quennell, who was unmarried, joined the B.M.A. in 1912.

We regret to record the death on March 18 of Mr. **ASLETT BALDWIN**, consulting surgeon to the West London Hospital, to St. Mark's Hospital for Diseases of the Rectum, and to a number of other hospitals in and around London. Aslett Baldwin was a student of the Middlesex Hospital, qualified in 1893, and obtained the F.R.C.S. in 1896. He began and continued as a general surgeon, but combined this with more and more work in his chosen specialty. He made a number of practical contributions to the Subsection of Proctology of the Royal Society of Medicine, and after that had been raised to the rank of an autonomous Section he served as its president, and was also a Fellow of the American Proctological Society. Aslett Baldwin had been a member of the B.M.A. since 1908 and was a past-president of the West London Medico-Chirurgical Society.

Dr. **THOMAS JOSEPH COSTELLO**, an alderman and former mayor of Darwen, Lancs, died on March 3, aged 55. He studied medicine at University College, Dublin, and graduated B.Sc., M.B., B.Ch. of the National University of Ireland in 1913. After serving as house-surgeon at the Mater Misericordiae Hospital he was in the R.A.M.C. with the rank of captain during the last war, and won the Military Cross. As chairman of the Darwen Public Health Committee, to which he was elected in 1937, Dr. Costello did much good work in the borough in promoting the establishment of new public baths and a civic health centre. As an undergraduate he was one of the fastest three-quarter backs in Irish rugby football, and in his last year played in all three international matches against England, Scotland, and Wales.

Dr. **CHRISTOPHER HUGH MACKLIN**, of Ampthill, near Bedford, who died in London on March 27, was elected chairman of the North Beds Division of the B.M.A. in June of last year. He was born at Pidley, Hunts, on Nov. 19, 1894, son of the Rev. H. W. Macklin, and from Felsted School entered the Middlesex Hospital. After qualifying M.R.C.S., L.R.C.P. in 1921 he was appointed house-physician at the Middlesex, his hospital studies having been interrupted by three years' service as surg. sub-lieut., R.N.V.R., in H.M.S. *Orotava*. Dr. Macklin held a number of appointments at Ampthill from 1922 onwards, and at the time of his death was the senior member of a partnership of three.

Dr. **JOHN NAIRN MARSHALL** died at his home, Stewarthall, Isle of Bute, on March 15. He was in his 85th year and was born at Pollokshields, Glasgow. He graduated in medicine at Glasgow University, thereafter holding resident posts in the Western Infirmary, Glasgow, and Belvidere Fever Hospital, Glasgow. He then took his M.D. and went to Vienna for postgraduate work. After a short period of practice in Galston, Ayrshire, he settled in the Island of Bute in 1892 and continued in active practice there until he retired in 1934. He took a great interest in medical matters, holding at different times the offices of president of the Glasgow and West of Scotland Branch of the B.M.A., chairman of the Bute Insurance Committee, and chairman of the Victoria Cottage Hospital, Rothesay. He was a Fellow of the Royal Faculty of Physicians and Surgeons, Glasgow, and a member of the Marine Biological Association, Millport. He was largely responsible for the formation of the Bute Natural History Society in 1905 and for equipping the Bute Natural History Museum; he also undertook archaeological investigations in Bute. He was a Fellow of the Society of Antiquaries of Scotland. He is survived by his wife and three daughters—Miss Margaret Marshall, R.R.C., who is matron of the Royal Infirmary, Edinburgh, Miss Sheina Marshall, D.Sc., who is a biologist on the staff of the Millport Marine Biological Association, and Miss Dorothy Marshall, who is at home. The high regard in which Dr. Marshall was held by the Bute community was evidenced by a public presentation at the time of his retirement, this function being presided over by Lord Bute. Dr. John V. Thomson sends the following tribute: The moving finger that "writes and having writ moves on" must have recorded a noble story of Dr. Marshall, a story of trials that come from following the right rather than the expedient, of perseverance in well-doing, of human sympathy and kindness. His quietness of manner was a noteworthy characteristic which called forth the remark by one of his patients that "he could not have many idle words to answer for." His skill and knowledge as a physician and surgeon were of a high order, and on this account he was often called in consultation by his colleagues and neighbouring general practitioners. His work had the broad outlook of one well versed in natural history, and he recognized medicine as a jealous mistress who allowed to her devotees no counter-attractions. He had great kindliness and charm of manner, which, combined with wide reading and a retentive memory, made him a delightful host in a home where guests were the rule. In his earlier years in practice travelling was by bicycle, by riding, and by gig, and was in consequence especially strenuous. His experiences were rich, and it was entertaining and informative to hear him reminiscing. He was a staunch supporter of cottage hospitals and was a believer in general practitioners doing some of their own surgery. His services were freely given to the poor, and he was most lenient in the matter of fees. In all his activities he was ably and loyally supported by his wife and family. He had a wide circle of friends in the West of Scotland, who mourn his loss and whose sympathy goes out to his bereaved family.

Dr. **EDWARD WILLIAM REES-JONES**, late medical officer of health for Blackpool, died at Lytham St. Annes after a short illness on March 27. He had his medical education at University College, London, and the University of Glasgow, graduating M.B., Ch.B.Glas. in 1898 and M.D. in 1904; he also took the Cambridge D.P.H. Entering the public health service his first appointment was that of assistant M.O.H. for Nottingham; he was then deputy M.O.H. and school medical officer for Lincoln before taking up the post of M.O.H. and school medical officer, Blackpool. During the last war Dr. Rees-Jones held a commission as temporary captain, R.A.M.C. He joined the B.M.A. in 1906, was honorary secretary of the Blackpool Division for twelve years, and chairman in 1932–3. He was a Fellow of the Society of Medical Officers of Health, a Serving Brother in the Order of St. John of Jerusalem, and honorary surgeon to the St. John Ambulance Association. When he retired from his post at Blackpool in 1940, at the age of 65, he could look back on immense developments in the medical services of the town.

Dr. **JOSEPH KENNISH** of The Chase, Clapham Common, S.W., died on March 2. at the Bolingbroke Hospital, after a week's illness, aged 78. A Cumberland man by birth, he studied medicine at the University and Royal College of Surgeons, Edinburgh, and qualified L.R.C.P.&S.Ed. and L.R.F.P.S.Glas. in 1897. Thereafter he practised at Clapham, where he had been district medical officer to the Wandsworth Guardians and served to the end as one of that borough's public vaccinators. A keen B.M.A. man, elected in 1907, he was hon. secretary of the Wandsworth Division for many years and represented it at two Annual Meetings; he also served on the Ministry of Health Committee at headquarters in 1919–20. He did yeoman service during the last war as honorary secretary of the Local Medical War Committee, his work in that capacity being recognized both by the Central Medical War Committee and by his fellow practitioners in Wandsworth, who presented him with a gold watch. He had also been treasurer of the South-West London Postgraduate Association up to the time of his death. A. D. M. writes: Joseph Kennish was kindly, self-sacrificing, and lovable, a great favourite with all who knew him. In his student days "Jos.," as he was affectionately called by his Edinburgh contemporaries, was well known as a university harrier, sprinter, billiard player, and yachtsman.

Dr. **JOHN PATRICK O'KANE** was born at Swateragh, Co. Derry, in 1896, and came over to Preston with his family at an early age. After being educated at Ushaw College, Co. Durham, he joined the Life Guards in 1916. On his discharge in 1918 he entered the medical faculty at the National University of Ireland, where he graduated M.B., B.Ch., B.A.O. in 1925. After a period as house-surgeon at Bagot Street Hospital, Dublin, he returned to Preston and settled in general practice. In 1927 he was appointed honorary surgeon to St. Joseph's Hospital, Preston, and in 1934 lecturer to St. John Ambulance classes, a work in which he always took the greatest interest. He was a sick man for many months before he was compelled to take to his bed, but the interests of his patients were always foremost in his mind, and he worked among them until he could work no longer. After eight weeks of very patient suffering he died on March 20, at the age of 49. To his widow and three young daughters we extend our deepest sympathy.—L. F. U.

News has been received from South Africa of the death of Dr. **JOSEPH CECIL GILLESPIE**, for many years a member of the Natal Coastal Branch, of which he had been president. He was educated at Trinity College, Dublin, graduating B.A. in 1921, M.B., B.Ch., B.A.O., and L.M. of the Rotunda Hospital in 1922; a year later he obtained the F.R.C.S.I. diploma, and in 1927 the D.O.M.S. of the English Royal Colleges. Dr. Gillespie practised as an ophthalmic surgeon at Durban, and his position in that specialty was recognized by election as president of the Ophthalmological Society of South Africa. He published papers on subjective tests in errors of refraction and on the relation between dental and ocular affections. During the present war he served as ophthalmic specialist to the Durban Command.

The Services

Surg. Cmdr. J. M. Flattery, R.A.N., has been mentioned in dispatches for skill, determination, and courage while serving in certain of H.M. Australian ships in the Leyte Gulf operations.

Capt. A. J. Clarke, R.A.M.C., has been awarded the M.C. in recognition of gallant and distinguished services in North-West Europe.

The following appointments and awards have been announced in recognition of gallant and distinguished services in North-West Europe:

C.B.E. (Military Division).—Col. (Temp.) J. Melvin, O.B.E., M.C., T.D., R.A.M.C.

O.B.E. (Military Division).—Col. (Temp.) W. H. Marston, T.D.; Lieut.-Col. W. J. McIntosh, T.D.; Major (Acting Lieut.-Col.) D. H. Young; Majors (Temp. Lieut.-Cols.) A. McC. Campbell, D.S.O., M. Fallon, J. A. Finegan, C. E. Gallagher, R. L. Holt, F. Heywood-Jones, T.D., H. W. E. Jones, A. F. Kennedy, F. L. Ker, B. M. Nicol, G. E. Ord, and S. R. Trick, R.A.M.C.

M.B.E. (Military Division).—Capt. (Acting Major) K. D. Stewart; Capts. (Temp. Majors) D. E. H. Beattie, R. G. Evans, M. Hunter, J. B. Mackay, A. MacLeod, J. D. McLennan, and D. J. Watterson, R.A.M.C.

D.S.O.—Major (Temp. Lieut.-Col.) M. E. M. Herford, M.B.E., M.C., R.A.M.C.

M.C.—Capt. G. Karstaedt, R.A.M.C.

The following have been mentioned in dispatches in recognition of gallant and distinguished services in Burma and on the Eastern Frontier of India:

Brigs. (Temp.) G. J. V. Crosby, T.D., and H. G. Winter, M.C.; Col. A. C. Jebb, late R.A.M.C.; Col. (Temp.) J. H. Baird, R.A.M.C., Reserve of Officers; Cols. (Temp.) J. W. Eames, A. J. Gardham, and D. F. Panton; Cols. (Acting) J. R. Dawson and R. V. Franklin; Lieut.-Cols. (Temp.) F. P. M. Anderson, S. W. K. Arundell, N. Bickford, S. O. Bramwell, H. R. Hartnell, M.B.E., A. J. Martin, J. H. Moffett, J. J. O'Dwyer, M. E. D. Roberts, and E. J. M. Wenyon; Majors H. G. N. Cooper and R. H. Wheeler; Majors (Temp.) J. Brown, J. V. Crawford, E. A. Donegan, J. Duguid, K. J. Dunlop, J. C. Gregory, C. L. Hayshunker, A. Hunter, J. W. Montgomery, W. O'Callaghan, J. Smibert, B. E. C. Stanley, and R. K. A. Van Someren; Capts. N. H. Bloom, J. A. Chamberlin, H. D. Cockburn, K. C. S. Edwards, H. E. D. Flack, C. H. Foggitt, F. D. Forbes, A. T. Freeland, N. H. H. Golledge, A. D. Gould, J. Griffith, J. N. Hamill, E. A. Heaslett, T. K. Howatt, J. S. Mather, P. G. Miller, D. MacD. Milne, J. C. S. Paterson, E. Rea, R. S. Saxton, J. P. Scrivener, J. B. Stafford, L. L. Theron, and W. J. Watt; Lieut. E. J. Rubra, R.A.M.C. Brig. (Temp.) W. E. R. Dimond, C.I.E., O.B.E.; Cols. (Temp.) W. A. Burki, M.B.E., and F. R. Cawthorn, I.M.S.

Lieut.-Cols. (Temp.) P. H. Addison, B. C. Roy, D. F. Eastcott, W. A. Hopkins, G. A. Ransome, M. Shwe Zan, and M. L. Smith, M.C.; Lieut.-Cols. (Acting) A. K. Gupta and E. J. Currant; Majors (Temp.) K. L. Aich, P. Dass, D. G. Horan, P. A. Hubbard, A. N. Roy, G. Sambasivan, and A. D. Wilson; Major (Acting) L. E. Chaves; Capts. A. Ahmed, L. K. Anantharayanan, A. N. Ansari, T. D. Brown, P. N. Chatterji, W. A. Clark, Y. D. Deshpande, (Mrs.) B. F. Dickenson, D. B. Doctor, S. C. Dutta, A. E. Frazer Smith, R. Gardiner, G. Mandal, Y. D. Ghyasuddin Ahmed, M. L. Gupta, G. D. Shenoi, A. F. Hussain, M. M. A. Jabbar, R. Krishnamurti, T. L. W. McCullagh, A. Merriweather, V. Rangaswami, S. R. Turkhud, J. Shrinivasan, S. D. N. Sinha, S. Shapurji, and R. B. Tulpule; Capts. (Temp.) N. Choudri, D. G. N. Narayan, G. S. Sidhu, N. K. Mitra, N. Adisehiah, and S. G. Shah; Lieut. M. Saifullah, I.A.M.C., Capt. M. B. Lall, Burma A.M.C.

Freed by U.S. Forces.—Capt. Percy Bailes Barker, R.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Previously reported missing in Italy, now presumed killed in action.—Surg. Lieut. Alastair Simpson Bell McNeil, R.N.V.R.

Killed as the result of air action while a prisoner of war.—Capt. Robert James Finlay Howe, R.A.M.C.

Died of wounds.—Capt. Gordon Spencer Sheill, M.C., R.A.M.C.

Died.—Lieut.-Col. Gavin Alexander Elmslie Argo, O.B.E., M.C., R.A.M.C.; Capts. John Henry Richardson Barker and Diarmuid Declan O'Callaghan, R.A.M.C.; Lieut.-Col. James Scott Riddle, I.M.S.

Wounded.—War Subs. Capt. J. Breckenridge and Temp. Major J. L. Nicol, R.A.M.C.

DEATHS IN THE SERVICES

Lieut.-Col. **WILLIAM SIMPSON**, R.A.M.C., A.D.M.S., North Caribbean Area, is reported to have been drowned on March 18 outside Kingston Harbour, Jamaica, after falling overboard from a yacht.

He graduated in medicine at Glasgow in 1923 and proceeded M.D. four years later. In civil life he was obstetric surgeon to the Preston Royal Infirmary and consulting obstetrician to the Lancashire County Council and a number of voluntary and municipal hospitals. He had been resident physician at the Glasgow Royal Infirmary and Royal Maternity and Women's Hospital, and senior M.O. at St. Alfege's Hospital, Greenwich. Before his appointment to the North Caribbean Area Col. Simpson acted as hospital liaison officer between the War Office and the Ministry of Health.

Surg. Capt. Herbert Wells Bayly Shewell, R.N. (ret.), who died at the Royal Naval Hospital, Minterne, Dorset, on March 27 in his 73rd year, had studied medicine at Cambridge and St. Bartholomew's Hospital, graduating M.A., M.B., B.Ch. in 1898. For his services in the last war Capt. Shewell was created O.B.E., and at the Annual Meeting of the British Medical Association held at Cambridge in 1920 he was vice-president of the Naval and Military Section.

Lieut.-Col. Andrew Thomas Gage, C.I.E., LL.D., I.M.S. (ret.), died last month at Strathpeffer, Ross-shire, at the age of 73. He was educated in Aberdeen and became an M.A. of the University in 1891 and qualified with the M.B., C.M. in 1896. In 1894-6 he was assistant to the professor of botany of Aberdeen University and entered the Indian Medical Service in 1897. After a short period in military employment he was appointed assistant to the Superintendent of the Botanical Gardens, Calcutta, the late Sir David Prain, whom he succeeded on Sir David's retirement in 1906. This appointment included the directorship of the Botanical Survey of India and charge of the cinchona factory near Darjeeling, and involved much administrative work. His scientific publications included *A Botanical Tour in South Lushai Hills*, 1904, and *Vegetation of District Minbu* (Burma), 1903. When the Government of India decided to increase its cinchona plantations Col. Gage spent much time in touring over India in search of a suitable climate and soil for the purpose, and on his advice an area in Burma was chosen, but this was unfortunately lost to the Japanese early in the present war. He was awarded the C.I.E. for his services and retired in 1926. Shortly afterwards he underwent a very serious operation, made a good recovery, but had the misfortune to suffer later from a distressing cardiac condition which proved fatal. He was somewhat reserved in his manner, but was a thoroughly competent and reliable officer.

Universities and Colleges

UNIVERSITY OF OXFORD

In a Congregation held on March 20 the University accepted with gratitude an offer by Mr. Stanley Brookes of an annuity of £1,500 for seven years to further the study of the biochemical factors influencing organic mental disorders. Decrees were carried establishing a Betty Brookes Research Fellowship, in memory of the donor's daughter, for a period of not less than 7 years for the study of problems of brain metabolism in relation to nervous and mental disease, and prescribing conditions of tenure. The Fellow will be appointed by the Board of the Faculty of Medicine on the recommendation of the Whitley Professor of Biochemistry, to work mainly in the Department of Biochemistry, but also keep in regular touch with relevant clinical work, especially in the Nuffield Department of Surgery.

UNIVERSITY OF CAMBRIDGE

At a Congregation held on March 17 the following medical degrees were conferred by proxy except where an asterisk shows that they were received in person:

M.D.—H. B. May, E. Cronin.
M.CHIR.—J. M. Pullan, D. I. Williams.
M.B., B.CHIR.—G. N. Cooke, H. L. English, B. M. Heap, *M. L. Graeme.

UNIVERSITY OF MANCHESTER

Lord Woolton will be installed as Chancellor of the University on Wednesday, May 16. After his installation he will confer honorary doctorates on eleven persons, including Sir Wilson Jameson, M.D., F.R.C.P., Chief Medical Officer to the Ministry of Health, and Lady Limerick, Deputy Chairman of the British Red Cross Society.

UNIVERSITY OF ST. ANDREWS

The honorary degree of LL.D. will be conferred on William Thomson Munro, M.D., D.P.H., formerly medical superintendent of Glenlomond Sanatorium, at a graduation ceremony to be held on June 29.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Queen Mary has made a donation to the Restoration and Development Fund of the Royal College of Surgeons of England. The Fellows and Members of the College much appreciate the honour and are deeply grateful for this mark of Her Majesty's favour and approval.

Medical Notes in Parliament

Europe's Food

Earl Winterton on March 28 opened a debate in the House of Commons on supplies to liberated countries. He said the economic condition of the freed Western countries was resulting in malnutrition and was sowing the seeds of tuberculosis and deficiency diseases among children. Lack of vitamins reduced the physical powers of the inhabitants and almost abolished their powers of moderation and judgment. Unless Holland could be freed, hundreds of thousands of Dutchmen would die of starvation in the next six weeks. He was informed that U.S. Army rations were about twice those of the British Army in quantity, about four times those of the British civilian, and nine or ten times those of the average civilian in France. Mr. Greenwood said food supplies available in the world, apart from wheat, were likely to be lower this year than last. In the so-called liberated areas the problem would be something which the world had never seen, not even in the days of the Black Death. Disease germs knew no frontier, and this country might be as open to grievous diseases as those countries.

Mr. Attlee said that at the request of the War Cabinet he recently visited Paris, Brussels, and part of Holland to report on the situation. He reminded the House that Britain was a deficit area and could not supply other such areas, except at the expense of its own supplies. The duty of the military authorities to supply the people of the liberated areas was limited to provisions of an austerity standard. In any liberated area there were more than bare rations in the richer agricultural areas; greatest difficulties were in the poorer parts of the big towns. Military authorities were responsible for minimum needs not only of food but of clothing, blankets, soap, coal, and petroleum. Monthly demands of supplies were approved by S.H.A.E.F. and sent to Washington, and the supplies were brought to the country. These minimum supplies had sufficed to avoid disease. The standard was far lower than the standard in North America and was supplemented for heavy workers. But it was sufficient to maintain health, and up to now there had been freedom from epidemics. There was a danger of a world shortage in imported fats and milk products. In France the situation in the south was bad in places. In Belgium the food situation, though not easy, had been well held, as also in that part of Holland which had been liberated. In Holland still under the Germans the people received only about a quarter of the standard food in free Holland. This was utterly inadequate. Some food got in through the Red Cross, but not enough. The Allies were making plans to feed the people as soon as Allied troops got there. There would have to be specialized food for people near starvation. Provision must also be made for feeding displaced persons in Europe, and there was a prospect that the Allies would have to feed a great number of Germans. Up to the moment the Minister of Food had sent, or had agreed to release, for the liberated areas—which included some of the Mediterranean areas—900,000 tons of food from Britain's own stock.

Sir Arthur Salter said that rations for the normal person in France were not more than half British civilian rations. In Belgium they were much the same; in liberated Holland a trifle better; in unliberated Holland infinitely worse. Some food was going into Greece. In Yugoslavia there was great suffering on the Dalmatian coast, but relative plenty elsewhere. Commander Prior stated that in the South of France the percentage of premature births was increasing rapidly and the weight of the babies was poor. There was no milk and no baby foods. Dr. Haden Guest said he had been told by people of authority there that food conditions in Paris and in Belgium were much worse than they had been under the Germans. Sir Ralph Glyn pointed out that of 4,500,000 people in the western districts of Holland, 1,000,000 would not be physically able to digest ordinary foodstuffs. Mr. Emmott said his information from Rome was that 864 calories daily were available for Italian children, 890 for expectant mothers, and 1,600 for people in heavy work. No fats had been distributed.

Sir James Grigg, replying to the debate, said the problem looming in Northern Italy transcended any in Southern and Central Italy. Plans had been prepared to bring relief there. The service of someone with experience in the Bengal famine had been used to assist in investigating the need for bringing predigested food to areas of the Continent where ordinary food would be useless to the people for some time. The military would do their part to prevent disease in the wake of the Armies.

Colonial Medical Research

The Secretary of State for the Colonies and the Medical Research Council have jointly set up a Colonial Medical

Research Committee to advise them on medical research for the benefit of the colonies. The members are: Sir Edward Mellanby (chairman); Col. J. S. K. Boyd, R.A.M.C., Prof. P. A. Buxton, Dr. A. N. Drury, Brig. N. Hamilton Fairley, Dr. W. H. Kauntze, Prof. B. G. Maegraith, Dr. B. S. Platt, and Major-Gen. Sir John Taylor. The secretary of the committee is Dr. F. Hawking.

Artificial Insemination

Mr. Driberg asked on March 29 in how many clinics and by how many physicians experiments were now being conducted in the artificial insemination of women; how many children had been or were expected shortly to be born in Britain as a result of such experiments; how many of these children were the offspring of their mothers' husbands; how many of anonymous donors; and in the latter case, how the facts were recorded in the register of births. Mr. Willink answered that he had no information on the first part of the question beyond what had appeared in the medical press, from which he understood that artificial insemination had been carried out at a voluntary clinic at Exeter. On the subsequent parts of the question he had no information. So far as he knew, no births had been registered as resulting from artificial insemination.

Mr. J. Lawson asked whether the Minister was going to allow a practice of this sort, which was of great importance to this country, to be uncontrolled. Surely he could get the necessary legal powers? Mr. Willink said that obviously there was every possibility of this being a most difficult and controversial subject. He had given his reply on the information at present available, but it was clear the matter had many possibilities and many facets. He would consider what had been suggested and would consider what steps could be taken to obtain the desired information.

Mass Radiography Units

Mr. Willink on March 27 told Sir Wavell Wakefield that satisfactory progress was being made by the mass radiography units which had been brought into operation. Existing conditions did not yet permit any extensive application of the system, not only because of limitations on production of the highly specialized apparatus required but also because the present demands on medical man-power hindered provision of the expert staff essential for the proper use of the units.

Medical Students' Quota

In reply, on March 29, to questions by Dr. Summerskill and Mr. Messer, Mr. Willink declared it to be necessary, in order that man-power might be allocated in the best way, to fix quotas for the numbers of men and women to be admitted as medical students. The women's quota was fixed by reference to the number of women students admitted in the three years 1937–40. In addition a medical school which admitted both men and women could make good the deficiency in male students by admitting women. Neither the teaching staff nor the accommodation was at present available for extending teaching facilities. In statements of policy made by the Chancellor of the Exchequer on February 13 and by himself on January 18 the Government had given every encouragement to universities to formulate plans at once for the development of their medical schools as soon as conditions permitted, with special reference to the needs of women students.

Publications by M.O.s of Ministry of Health

Mr. Willink told Sir Robert Tasker on March 27 that the medical staff employed by the Ministry of Health were subject to the rule, applicable to civil servants generally, which required the sanction of the head of the Department to the publication of any book or work the subject-matter of which was connected with their official duties. This did not preclude them from communicating with medical journals on general professional matters. There was, for example, no obstacle to a medical officer of his Department making any communication to the medical press on a technical subject which might be of interest or advantage to medical science.

Accommodation for Tuberculosis in Wales.—Building work, which is expected to be completed within the next six months, is proceeding at the Glan Ely and Cefn Mably Tuberculosis Hospitals to provide 96 additional patient beds. 150 beds have also been secured at the Ministry of Pensions Hospital, Chepstow, and are being brought into commission as staff becomes available. Persons awaiting admission to sanatoria in Wales number 729.

Notes in Brief

Mr. Johnston hopes to announce shortly the composition of a committee to consider the position of children in Scotland who are deprived of a normal home life.

Medical News

The King has approved the appointment of the Hon. Walter Symington Maclay, M.D., to be a Senior Commissioner of the Board of Control (Lunacy and Mental Deficiency) on the retirement of Sir Hubert Bond from the public service on March 31. Dr. Maclay's most recent post has been that of medical superintendent of the Mill Hill Emergency Hospital. He held earlier appointments at the Maudsley and the West London Hospitals.

Radiological meetings, to be held in London, are announced as follows: at British Institute of Radiology, 32, Welbeck Street, W., Thursday, April 19, 8 p.m., Silvanus Thompson Memorial Lecture by Prof. E. A. Owen; at Royal College of Surgeons of England, Lincoln's Inn Fields, W.C., Friday, April 20, 2.30 p.m., Skinner Lecture by Mr. G. F. Stebbing, "Diagnosis of Cancer in a National Medical Service"; at British Institute of Radiology, Friday, April 20, 4.45 p.m., Mackenzie Davidson Memorial Lecture by Dr. J. F. Brailsford, "Reflections on the Teaching of Radiology"; at Royal Society of Medicine, 1, Wimpole Street, W., Friday, April 20, 6.30 p.m. (joint meeting of R.S.M. Section of Radiology, the British Institute of Radiology, and the Faculty of Radiologists), discussion on "Standardization of Radiological Apparatus," to be opened by Drs. Frank Ellis, J. W. McLaren, and J. Read. The annual meeting of the Faculty of Radiologists will be held at Leeds on Friday and Saturday, June 29 and 30 (*not* on June 28 and 29 as previously announced).

A meeting of the London Association of the Medical Women's Federation will be held at B.M.A. House, Tavistock Square, W.C., on Saturday, April 21, at 3 p.m., when there will be a discussion on the Negotiation Report of the B.M.A. Council.

Col. Oliver Stanley, Secretary of State for the Colonies, is announced as the chief speaker at a meeting at the Mansion House, London, on Thursday, April 26, at 3 p.m., to mark the 21st anniversary of the foundation of the British Empire Leprosy Relief Association. The Lord Mayor will preside. The meeting will inaugurate a campaign by the Association to raise a sum of £210,000 (that is, £10,000 for every year of its existence) in an intensified effort to eliminate leprosy from the Empire, which contains some two million sufferers. Plans include greater research, the provision of new clinics and agricultural colonies, and a redoubling of existing activities.

A meeting of the Clinical Society of the Royal Eye Hospital will be held at the hospital on Friday, April 27, at 5 p.m., when a talk on "Nystagmus" will be given by Mr. T. E. Cawthorne.

Prof. M. Greenwood, F.R.S., will give six public lecture on "Medical and Social Comparisons between the Conditions of England in the Wars against Bonaparte and Hitler" at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, W.C., at 4 p.m. on Monday, April 30, Wednesday, May 2, Monday, May 7, Wednesday, May 9, Monday, May 14, and Wednesday, May 16.

At a meeting of 40 urological surgeons under the chairmanship of Sir Alfred Webb-Johnson, P.R.C.S., held at the Royal College of Surgeons on March 17, it was decided to form the British Association of Urological Surgeons with the object of promoting a high standard in the practice of urology. The following officers were elected: *President,* Mr. R. Ogier Ward. *Vice-President,* Mr. Bernard Ward. *Hon. Secretary,* Mr. E. W. Riches. *Hon. Treasurer,* Mr. John Everidge. *Hon. Editorial Secretary,* Mr. H. P. Winsbury-White. *Members of Council:* Messrs. A. Wilfrid Adams, David Band, Arthur Jacobs, J. B. Macalpine, T. J. Millin, A. Clifford Morson, R. H. O. B. Robinson, and C. A. Wells.

One of the candidates for the Motherwell (Lanarkshire) Parliamentary by-election is Dr. Robert D. McIntyre, standing as a Scottish Nationalist.

A *Supplement* to the *London Gazette* dated April 5 contains a long War Office list of mentions in recognition of gallant and distinguished services in Burma and on the Eastern Frontier of India, included in which are the names of two civilian medical practitioners, Dr. C. G. Terrell and Dr. Wenefride Thompson, O.B.E. Dr. Terrell is a lieut.-col. in the A.F.M.C. and medical officer to the Surma Valley Light Horse. In 1931–2 he was president of the Assam Branch of the B.M.A. Dr. Thompson is the medical officer in charge of St. Luke's Hospital at Chabua, Assam.

At a special general meeting of the British Institute of Radiology called to consider proposed alterations to seven of the Articles of Association, a majority of those present approved the proposed alterations: this majority was, however, insufficient to permit any change in the articles, because the Companies Act requires a three-fourths majority, which was not obtained. There will therefore be no change made in the articles of the Institute. Approximately 70 members attended the meeting: the final voting on the special resolution was 29 in favour and 22 against, with 2 abstentions.

Dr. J. C. R. Buchanan, Deputy Director of Medical Services in Uganda, has left for Fiji to take up the post of Inspector-General of South Pacific Medical Services.

Sir Edmund Spriggs, K.C.V.O., has been appointed Sheriff of the County of Denbigh for 1945.

Dr. Hubert O'Meara, medical practitioner, has been commended for brave conduct in civil defence.

The *Bulletin of the History of Medicine* for October, 1944, contains an obituary notice of Sir Humphry Rolleston.

The medical report for 1943 of the Glasgow Royal Maternity and Women's Hospital records the retirement of Prof. S. J. Cameron in June of that year after 33 years on the hospital staff. Prof. James Hendry, now regius professor of midwifery in the University of Glasgow, was appointed medical director of the hospital from October, 1943.

Sir Jack Drummond, D.Sc., Scientific Adviser to the Ministry of Food, has been elected president of the Milk Publicity Council for 1945–6.

The Mayor and Mayoress of Oldbury, near Birmingham, Councillor and Mrs. C. T. Barlow, and their four children are providing a trust fund of more than £50,000 for a new maternity home in the borough. The corporation will assume responsibility for the upkeep of the home, but Councillor and Mrs. Barlow have given £2,000 as the nucleus of a fund to help deserving cases.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* the epidemic of measles continues, 241 more cases being recorded than last week; notifications of scarlet fever, whooping-cough, and diphtheria were respectively 99, 74, and 59 fewer. Lancashire had 43 fewer cases of whooping-cough than last week, and Yorks West Riding 34. The fall in diphtheria was also mainly due to two areas—Lancashire, which had 28 fewer cases than the previous week, and Yorks North Riding, which had 27 fewer. The increase in measles was due to the rise in the south, while in most northern areas the peak of the epidemic appears to have been reached a week or so ago. The largest local increases over last week's totals were Gloucestershire 177, Northumberland 120, Glamorganshire 118, Oxfordshire 114, London 103, Devonshire 92; while the largest falls were Yorks West Riding 330, Yorks East Riding 203, Hertfordshire 125, Warwickshire 90.

For the third consecutive week notifications of dysentery exceeded 400. The largest returns were London 69, Lancashire 59, Yorks West Riding 40, Northumberland 27, Surrey 26, Gloucestershire 17, Essex 16, Somersetshire 14, Suffolk 14, Durham 12, Warwickshire 11.

In *Scotland* there were 205 notifications of dysentery, a decrease of 47; the largest returns were Edinburgh 73, Glasgow 33, Falkirk 16, Lanark County 11. Increases were recorded for measles 79, whooping-cough 23, and diphtheria 9.

In *Eire* there was a rise in the incidence of measles 23, and whooping-cough 23. The increase in measles was contributed by Dublin C.B., where the cases rose from 14 to 36.

In *Northern Ireland* notifications of measles were 13 fewer than last week, scarlet fever 7 fewer, and whooping-cough 9 fewer; diphtheria notifications rose by 2.

Cerebrospinal Fever

The trend of cerebrospinal fever during the first weeks of this year was similar to that of 1944. The rise to a peak which was a feature of the outbreak of 1940 and the succeeding years was not apparent. This disease seems to have settled to its pre-war course—a summer minimum and a winter maximum—but at 2 to 3 times its former level. The number of cases during the first 12 weeks of the year in England and Wales was:

Weeks	Average of 1936–9	1940	1941	1942	1943	1944	1945
1–3 ..	98	304	785	459	271	226	179
4–6 ..	91	889	984	501	338	193	251
7–9 ..	107	1,759	1.212	567	293	195	226
10–12 ..	98	1,620	1,031	705	279	278	246
Total ..	395	4,572	4,012	2,232	1,181	892	902

Week Ending March 31

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,361, whooping-cough 1,123, diphtheria 495, measles 22,183, acute pneumonia 746, cerebrospinal fever 66, dysentery 394, paratyphoid 4, typhoid 8.

No. 12

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended March 24.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

---

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, London, W.C.1. Telephone: EUSTON 2111. Telegrams: *Aitiology Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). Telephone: EUSTON 2111. Telegrams: *Articulate Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. Telephone: EUSTON 2111. Telegrams: *Medisecra Westcent, London*.

B.M.A. Scottish Office: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Administration of Soluble Barbitone

Q.—*What are the dangers of continued administration of soluble barbitone? A woman of 51 first consulted me two years ago asking for a repetition of a prescription for gr. 10 nightly, which she had taken consistently for a long period following partial thyroidectomy. Less than 10 grains she finds useless. Am I justified in allowing her to take it indefinitely?*

A.—There is no danger in the continued administration of soluble barbitone *per se*, as neither addiction nor tolerance is developed for barbiturates. In this respect they differ fundamentally from morphine and cocaine. The present phenomenon is one of habituation, and the danger is in the personality of the patient rather than the drug. Both sleeplessness and fear of sleeplessness are symptoms of an anxiety neurosis, and the tablets of barbiturate have probably not only a pharmacological but a psychological significance for the patient. They have probably become an essential part of the sleep ritual, just as being "put down" or "tucked in" may be for a small child. Ideally, the anxiety neurosis should be relieved by psychological treatment, when the sleeplessness will disappear. In practice lasting success from psychotherapy is unlikely when the patient is aged 51, and when the psychological disturbance has been so profound that a toxic goitre has developed. Administration of soluble barbitone may therefore be the best form of symptomatic treatment, and in these circumstances the practitioner is perfectly justified in allowing the patient to continue the treatment indefinitely.

E.E.G. and Diagnosis

Q.—*How far has electro-encephalography progressed as a diagnostic measure?*

A.—Electro-encephalography has for the past eight years been in routine use in many neurological centres. In the Services evidence obtained by the E.E.G. is used for purposes of invaliding, and similar evidence has been accepted in capital charges. There is now an extensive literature upon the subject, and an excellent review has just been published by D. B. Lindsley in *Personality and the Behaviour Disorders*, edited by J. McV. Hunt, Ronald Press, New York, 1944, vol. 2, chapter 33. The seventy pages of the review give a very clear picture of the present position of clinical electro-encephalography. The technique is used particularly in the diagnosis of epilepsy and allied disorders, in investigating behaviour disorders, in following the progress of head injuries and revealing intracranial complications of trauma, and in demonstrating the presence of abnormal brain tissue in any cerebral disorder, whether it be neoplastic, inflammatory, or degenerative. The important thing to realize about the E.E.G. is that it can rarely be used without reference to all the other clinical evidences of disease. A full history, a careful examination, and an expert appraisal of all the evidence, including that obtained from the E.E.G., are essential if diagnostic accuracy is to be achieved. An absolute diagnosis of epilepsy can be made on the E.E.G. evidence alone only if the electrical equivalent of an attack happens to be seen on the record. The E.E.G. does not locate a cerebral tumour but the abnormal brain associated with it, and in trauma the E.E.G. findings can be interpreted only if the story of the illness is known. If this approach is employed, the E.E.G. seems to have come to stay.

Asthma and Smoking

Q.—*An active male aged 58 has to deny himself all social engagements, theatres, meetings, etc., because both smoking and tobacco-laden air precipitate in him attacks of bronchial asthma. He gave up smoking for the above reason a few years ago. What can be done?*

A.—Apparent tobacco sensitivity may be due to a non-specific irritation of the smoke dust inhaled or to a specific sensitivity to the tobacco itself. In crowded atmospheres, added to the non-specific irritation of tobacco smoke, there may be a specific sensitivity to house dust, face powder, and animal hairs also present; in cases reacting on smoking, sensitivity to materials used in flavouring (perfumes and oils), to ingredients of the papers used or materials employed in sticking them, or even a mould that grows on the tobacco, should be considered. In many instances the morning smokers' cough or wheeze may be due to a sensitivity to feather or down pillows. The patient should be tested intradermally with most of the above-mentioned common irritants; he should then be desensitized with those which give a positive reaction, and he should avoid so far as possible the specific causes of his trouble. Solutions for testing and treatment can be obtained from Messrs. C. L. Bencard, Gorgate Hall, Dereham, Norfolk. A cream of ephedrine 2% and benzocaine 4% may be applied to the nose before exposure, and half a grain of ephedrine hydrochloride by mouth gives temporary relief.

Penicillin in Chronic Sinusitis

Q.—*Is penicillin effective in chronic nasal sinus infection by displacement, where the organisms are sensitive? What strength should be used, and how often should it be done?*

A.—The organisms most commonly implicated in chronic paranasal sinusitis are the pneumococcus, haemolytic streptococcus, *Staph. aureus*, and *H. influenzae*, all of them, with the exception of the influenza bacillus, sensitive as a rule to penicillin. It would therefore seem reasonable to recommend local penicillin therapy by the "displacement" method (see Russell, *Proc. roy. Soc. Med.*, June, 1944, p. 401) for the cure of these intractable infections. There are, however, two difficulties: (1) treatment by displacement does not allow continuous action by the instilled penicillin, since when the patient resumes his normal position the drug will after 5 to 10 minutes drain away from the sinuses; (2) penicillin treatment of chronic infections generally has been rather disappointing, probably because the focus of infection is not easily reached and the lining membranes are so unhealthy that they do not assist in destroying the invaders. However, if the infection is shown to be due to a penicillin-sensitive pathogen local treatment by displacement may be tried, using a strength of 500–1,000 units of penicillin per c.cm. and repeating the treatment three times daily if possible for 7 to 10 days. Bacteriological control during and after treatment is advisable in order to find if the organism has been eliminated.

Degenerative Changes in Intravertebral Disks

Q.—*A man aged 65 has suffered for the last 18 months from osteo-arthritis of the cervical vertebrae. X-ray film shows marked diminution in the intervals between the bodies of C. 5, 6, and 7, with small amount of destruction of bodies of 6 and 7; appearances are those of a subacute bone infection. There is obvious lipping and proliferation of bone. The orthopaedists do not agree that there is either any destruction of bodies or bone infection. Subjectively there is a wearisome perpetual tingling like electricity, with occasional aching, in left neck, but no limitation of movement. Cracklings are heard and felt on turning head. I have tried manipulation under pentothal, diathermy, deep x rays, infra-red, and U.V. rays. Deep x-ray treatment gave much relief for a time. If this radiculitis is caused by pressure of bone on nerve roots why should not operation give relief, and why do orthopaedists refuse it?*

A.—This symptom complex is not uncommon, though varying widely in type and severity. Degenerative changes in the intervertebral disks in the cervical region are so frequently seen in lateral *x*-ray views in later middle life as to be almost a normal development, though often symptomless. This was demonstrated by Schmorl, whose work has been made accessible to British readers in Beadle's monograph. The condition is the result of the great mobility of this part of the vertebral column. The disks gradually lose their elasticity and shrink, increased play between the vertebrae results, and osteo-arthritic changes follow, with lipping of the bodies and formation of exostoses at the points of attachment of ligaments and muscles. Often there is seen some degree of crushing of the vertebral bodies themselves. Watson-Jones has called attention to changes in the cervical spine in early life as a result of inflammatory conditions in the throat, but in the cases seen after middle age there is usually no history of throat trouble and the condition is not infective but degenerative. As is commonly the case in osteo-arthritis, there is usually more or less fibrositis of the muscles and intervertebral structures, and the crackling which can be heard and felt is due to this and does not originate in the vertebral articulations. Pain down the arms is a common symptom and is due to irritation of the nerve roots through the narrowing of the foramina from the thinning of the disks, or to fibrositis of the roots, which swell and fill the foramina, or to the pressure of exostoses. In the present case it seems that the posterior branches of the cervical nerves are chiefly affected.

Heat and massage, if persevered with, generally give relief. Often moist heat is more effective than radiant heat, but cannot be used so readily with massage unless the massage is given first—the latter often being the most effective procedure. Manipulation may easily do more harm than good. Ionization with histamine is a useful method which can be used in combination with massage. Since most of these methods appear to have been tried already, strong counter-irritation is worth a trial; the most convenient method which does not interfere with the patient's normal avocations is the electric cautery; a light application on either side of the cervical spine two or three times a week will act on the posterior nerve roots.

Operation on the foramina in this region would be a rather hazardous procedure and success could not be guaranteed. Further discussion of the subject, with references, will be found in an annotation in the *B.M.J.* of Nov. 9, 1940 (p. 635), and also in the *Reports on Chronic Rheumatic Diseases* (London: H. K. Lewis), 1, 128. Oppenheimer of Beyrout has made a special study of the condition, which he calls "discogenetic disease" (*Amer. J. Surg.*, 1940, **47**, 642).

Submucous Injection of Haemorrhoids

Q.—*What is the correct chemical and its strength for submucous injection of haemorrhoids?*

A.—The following prescription has been used for 15 years with consistent success and safety. A stock solution is made of equal quantities of phenol crystals and almond oil (if none available, arachis oil), and 20 grains of menthol to the ounce. For use, one part of the stock solution is taken to nine parts of almond oil (or arachis oil). The average dose is 3 to 6 c.cm. per haemorrhoid, and in skilled and experienced hands two haemorrhoids may be treated at a time; otherwise, the safe method is to do one haemorrhoid a week. It must never be put in so that it causes a blanching of the mucous membrane, as this will be followed by sloughing and ulceration. It is injected well above the haemorrhoid, when it is quite painless.

Musculospiral Palsy

Q.—*A man of 60 fell asleep in a deck chair. When he woke up he was able to write only in a distorted manner; his little finger was in the way and would not support his hand; he could write on a blackboard. He was able to shave with a "cut-throat" razor but could not strop it since he could not turn it over. His right little and ring fingers were slightly flexed and could not voluntarily be fully extended. There was gradual improvement and full recovery. He was told he had had a "small stroke." Is this the likely diagnosis?*

A.—This patient would seem to have had a partial lesion of his musculospiral nerve caused by the pressure of his arm upon the chair. He need therefore have no anxiety about a stroke.

Ptyalism in Pregnancy

Q.—*Can you suggest any treatment for the excessive salivation of pregnancy? It is occurring in a healthy woman who is having progesterone because of a previous miscarriage, and multiple vitamin tablets for general nutritive purposes.*

A.—The cause of excessive salivation in pregnancy is unknown and its treatment is therefore empirical. I do not know of any treatment other than that recommended in the standard textbooks: astringent mouth-washes such as 1% alum, belladonna or atropine pushed to the limit of tolerance, sedatives such as bromides, simple diet with plenty of fluids, and attention to the bowels. Daily intramuscular injections of 10 c.cm. of 10% calcium gluconate are recorded as curing some cases. Neurosis often plays a large part in the aetiology, and the results of treatment are mainly disappointing. However, ptyalism tends to disappear as pregnancy advances, usually by the fifth month.

There is a theory that toxaemias of *early* pregnancy are due to an abnormal sensitivity to corpus luteum hormone, and it is just possible that the progesterone therapy is causing excessive salivation in this case. At any rate it would be worth while discontinuing treatment to see if there is any improvement in symptoms, but it would probably be unwise to go so far as to administer oestrogens, as the patient has already had one abortion.

Congenital Syphilis

Q.—*What is the latest age at which the symptoms of congenital syphilis can be manifested? For example, a patient aged 30 has a "saddle-back" nose and suffers from severe occipital headaches. The hair has been coming out, and treatment with thyroid makes no difference to this. Would one at this age expect to find a positive Wassermann in blood or cerebrospinal fluid?*

A.—Signs of congenital syphilis may appear, or at all events be brought to the doctor's notice, at almost any age. For example, Dennie recorded a case of congenital syphilis affecting the tibia in a man of 45, Pinard one of gumma of the clavicle at 73 years, and Lazarescu a case of interstitial keratitis in the decade 60–70; eighth-nerve deafness has been recorded up to 38, and congenital tabes in a patient of 50. Disorganization of the bones of the nose is usually due to destruction by gumma formation, with resulting "saddle-back" deformity, and may occur at any age; occipital headaches may be due to neurosyphilis, but also to other conditions. In this case an examination of the cerebrospinal fluid may settle the matter. Alopecia is rare in late congenital syphilis. Positive serum reactions usually tend to weaken or revert to negative with the lapse of time, but may persist throughout life.

Signs of congenital syphilis are usually divided into early and late or tardy. In general, the acute signs are most commonly seen in *infants*, and correspond with the secondary stage of acquired syphilis; these include generalized rashes, snuffles, the aphonic cry, rhagades, enlarged spleen, osteochondritis, and pseudoparalysis. In *children* the signs tend to become more localized and to affect single organs or systems. At this time the Hutchinsonian triad—interstitial keratitis, characteristic teeth, and eighth-nerve deafness—is most commonly met with, together with the typical facies, neurosyphilis, and signs of mental retardation. In the *adolescent* and *young adult* interstitial keratitis is the commonest sign, and in the *adult* bone and localized skin lesions predominate, corresponding with the tertiary stage of the acquired form. Active signs rarely appear after the age of 30, but many of the classical ones are permanent and persist throughout life. Serum reactions are almost always positive in the presence of active signs, but as the lesions tend to become localized and cease to progress, so the blood reactions tend to weaken. It is clear, therefore, that the older the patient the less the value of a negative reaction in excluding a diagnosis of congenital syphilis.

Yaws and Positive Kahn

Q.—*In the African wing of a general hospital which admits East and West Africans and Basutos, many have a two plus, three plus, or four plus Kahn. A large number admit to being promiscuous, but few have noticed genital sores. Many for no apparent reason have high E.S.R.s. As yaws is prevalent in most of Africa difficulty is experienced in interpreting the result of the Kahn test. Will yaws in childhood still have a strongly positive serological test in adult life? In the absence of clear clinical signs, should even a persistently strongly positive Kahn be ignored in an African? Have the weaker positive Kahn results any significance in an African suffering, for instance, from such a condition as monarticular synovitis of unknown causation?*

A.—Many Africans in localized yaws endemic areas have positive Kahn reactions, attributable to an inadequately treated yaws infection. In other areas, where yaws is not endemic—and there are many of them in West Africa—syphilis is common, and a positive Kahn test would suggest this infection. If a positive Kahn is due to yaws a couple of short courses of N.A.B. would almost certainly reverse it, but this would probably not be the case if it were due to syphilis. The Kahn test may also be rendered positive by such diseases as leprosy, malaria, and trypanosomiasis. Thus the cause of a positive Kahn test in the absence of any history of the exact geographical origin and of the previous medical history and present condition of the patient is speculative.

In an African a one or two plus Kahn can usually be disregarded, and it is unlikely that a three or four plus Kahn test in adult life in the absence of any current evidence of the disease could be attributed to a cured childhood infection with yaws. It is more probably due to syphilis. There are certainly exceptions to this generalization, but the extent to which they occur rests on personal opinion and not on any very solid statistical analysis.

Reactions after Inoculation

Q.—*It is recommended that after inoculations with T.A.B., etc., the patient should take no alcoholic drinks. What is the scientific explanation of this instruction?*

A.—Reactions, both local and general, may occur after prophylactic vaccination, particularly with T.A.B. vaccine. In order to minimize the degree of reaction it is usually advised that the injection be given as late as possible in the day, preferably not more than 6 hours before bedtime, that the patient be excused heavy muscular exercise during the following 24–48 hours, and that he avoid any excesses, such as abuse of alcohol. There is no scientific reason for the avoidance of alcohol apart from the fact that excess of alcohol may itself temporarily lower resistance, and the combined effect of a "night out" and the T.A.B. injection may produce a more severe reaction than would otherwise occur. Such advice would not exclude the use of a "night-cap" if the patient were feeling seedy, although 5–10 grains of aspirin would probably be preferable and more accessible.

Headache after Fractured Skull

Q.—*A patient 30 years ago had a fractured skull, probably basic, and was unconscious for six weeks. She recovered, but two or three times a week ever since has been subject to bad headaches at the back of the head—not acute pain but a heavy ache with a mentally fuddled feeling—and they last for hours. Suggestions for relief would be welcomed.*

A.—A post-traumatic headache of this sort may unfortunately persist indefinitely. There is no method of local treatment which is likely to relieve the patient. The pain probably arises in the blood vessels and the dura mater of the posterior fossa, which is supplied by small sensory branches of vagus nerve. All the dura above the tentorium is supplied by the fifth, but practically all that of the posterior fossa is supplied by recurrent meningeal twigs of the tenth cranial nerve. These are not accessible to surgical intervention. Air replacement of cerebrospinal fluid is said to relieve some of these cases, the argument being that pain-producing adhesions are broken down, but I have been unable to confirm these observations. As all the usual analgesic mixtures and tablets must have been tried in this case, I am unable to make any useful suggestions.

Legal Responsibility of Service Doctors

Q.—*What is the legal position of Service medical officers as regards responsibility for professional care, etc.? Through many years' denial of clinical experience we have been reduced through no fault of our own to a low state of professional ability. Are we or the employing Service held responsible if we are charged by a patient with negligence? If we are legally liable, then we should have the right to refuse to treat any patient whom we do not consider ourselves capable of treating satisfactorily.*

A.—The question does not make quite clear whether the practitioner is still in the Service or not. In either case, however, he owes the same duty to exercise that degree of care and skill which a reasonable man would expect having regard to all the circumstances. If he is still in the Service he may not find himself in a position to refuse to treat a patient on the ground that he is out of practice in the particular procedure required. If he makes every legitimate effort to excuse himself but is nevertheless ordered to perform the procedure and harm results, he probably has a good defence. He may, however, rest assured that the risk of a Service patient suing a Service doctor for negligence is quite negligible. If he has left the Service he performs an unfamiliar procedure at his own peril. It is always open to him to refuse to treat the patient. Doubtless, Service conditions are to blame for his lack of skill, but no court could be persuaded to hold it responsible.

INCOME TAX

Newcomer from Eire

M. has recently come to this country from Eire. His inquiries will be sufficiently clear from the following replies.

*** There is no interval of six months before liability to income tax begins to accrue where the income is derived from work in this country. No allowance is due in respect of the costs of a sister's education. Presumably M. cannot show that "he has the custody of and maintains" his sister, and cannot therefore claim the child allowance for her; the allowance in respect of dependent relatives does not apply, as that allowance is restricted to relatives "incapacitated by old age or infirmity." Tax should be deducted by M.'s employer as and when remuneration is paid to him. The amount of his liability (and of the tax deductions) will depend during the present year on the amount of his earnings in this country, and therefore cannot be estimated without knowledge as to the date from which the remuneration of £10 10s. weekly began.

Resident Quarters

O. D. is employed as a resident M.O. at a Ministry of Pensions hospital. He "lives in"; his quarters consist of one small bedroom. The annual value is assessed at £12, and he has been applied to for the tax thereon at the standard rate of 10s. in the £.

*** The position is that the hospital is entitled to exemption from tax, except as regards such portions as are occupied by officers who are liable to income tax. The charge therefore arises by restriction of an exemption enjoyed by the hospital authority. The tax is legally payable, but whether by the authority or the individual officer is a matter which is governed by the agreement under which the officer is employed. £12 may be somewhat excessive for such accommodation, though an appeal is not likely to be successful. Our correspondent may be able to find out whether similar accommodation (unfurnished) is available in the neighbourhood at appreciably less than 5s. per week.

Tenant under Furnished Letting

"Orion" rented a furnished house for a period of years, paying a rent of £4 per week and being responsible for all repairs, for breakages, and for payment of £150 for dilapidations. Can he claim any allowance for these payments?

*** It is assumed that the premises were not used for professional as distinct from personal purposes. In that case the reply is that no allowance is due. The payments amount to an aggregate rent, and represent payments out of income; the landlord will be liable to account for tax on his total profit less any expenses of reinstatement paid out of the amounts he receives.

LETTERS, NOTES, ETC.

Subacute Combined Degeneration of Cord

Dr. Brendan O'Brien (Dublin) writes: With reference to the note on subacute combined degeneration of the cord (Feb. 3, p. 172), it may be of interest to quote a case which I saw last year. The patient, a man of 50, a works foreman by occupation, came to the Meath Hospital, Dublin, suffering from such severe ataxia that he could not go about by himself nor do his work. Tabes having been excluded, blood tests and a fractional test meal were performed, with subacute combined degeneration in mind. Blood count was: red cells, 5,250,000 per c.mm.; Hb, 90%; white cells, 7,500 per c.mm. When plenty of free acid was found in the test meal this diagnosis was discarded, and various methods of treatment were attempted and were completely ineffectual. Eventually, on the suggestion of Dr. H. Lee Parker, full doses of liver, as mentioned in your note, were administered, and the patient made a most dramatic recovery and has been back at work for the last six months. There is now only the slightest degree of spasticity about his gait. It would appear from this that the presence of free hydrochloric acid in the stomach does not exclude a nervous condition which may respond to liver therapy.

Pain from Crystal Violet

Dr. M. Ghosh (Burton-on-Trent) writes: In those cases of varicose ulcer and eczema when the patients complain of pain due to the application of crystal violet (*Journal*, Feb. 24, p. 282), I have found the addition of 1% butethanol or benzocaine to 2% solution of crystal violet in water uniformly successful.

Attacks of Cyanosis and Giddiness

Dr. Arthur Howard (Monmouthshire) writes: I notice (Feb. 3, p. 173) your answer to a question on attacks of cyanosis and giddiness coming on only through exertion. Surely this history is typical of the symptoms caused by a congenital heart lesion? It would be interesting to know the result of cardiography taken in oblique, lateral, and A.P. positions.

Dupuytren's Contracture and Cavernous Angioma

Dr. E. Millington (Hove) writes: The answer to the query about Dupuytren's contracture in the issue of March 10 (p. 354) gives a very dismal outlook and suggests that no treatment is possible. I have treated a large number of these cases very successfully during the past few years with *x* rays, and had thought that their use was more widely known in this connexion. The technique most commonly used is similar to that employed in the treatment of other condensations of fibrous tissue such as keloids, fibromata, and adherent scars, and consists of applications of about 300 *r* every three or four weeks for from 6 to 10 treatments, varying with the size of the lesion. As a rule the fibrous mass slowly disappears during the course of treatment, leaving no visible scar, though advanced cases of Dupuytren's contracture may require a subcutaneous fasciotomy in addition, which is a very minor procedure. Even without employing *x* rays very early cases often clear up with no other treatment than hyperextension exercises to the affected fingers carried out regularly for some months, with the addition of a night splint in suitable cases.

The answer about treatment of cavernous angioma in the same issue (p. 354) also makes no mention of radiotherapy, but advises surgical excision. The majority of these vascular tumours respond extremely well to either radium or *x*-ray treatment, and it would seem well worth trying rather than proceeding at once to what is quite a tricky operation.

Recurrent Boils

Dr. R. H. Georges (Virgin Islands) writes: With reference to treatment of recurrent and other attacks of boils (Nov. 11, 1944, p. 649), might I be permitted to suggest another method which I have used throughout last year and have found most effective. Small injections of bismuth in 1/2 to 1 c.cm. doses, according to size of patient, administered into the gluteal region once a week for 3 to 4 weeks, appear to effect a cure in all cases in my limited experience. Very often when the patient has reported for the second injection the boil or boils will have been aborted, but it has been found advisable to continue another 2 or 3 injections in order to prevent further attacks coming on within a short space of time. This form of treatment has been used, with success, in all staphylococcal skin infections, including impetigo and secondarily infected skin rashes. Seldom does local treatment of any sort appear necessary.

Medical Aphorisms

Mr. W. R. Le Fanu, M.A., Librarian of the Royal College of Surgeons of England, writes with reference to Dr. Crawhall's inquiry (March 31, p. 470): There is a good survey of "Medical Aphorisms, chiefly in English" by the late Sir Humphry Rolleston in the *Bulletin of the History of Medicine*, Baltimore, Nov., 1941, vol. **10**, pages 544–67.

TWO SCHOOL OUTBREAKS OF STREPTOCOCCAL THROAT INFECTION

THE EFFECT OF SULPHONAMIDE LOZENGES ON CARRIERS

BY

R. L. VOLLUM, M.A., D.Phil.

AND

G. S. WILSON, M.D., F.R.C.P., D.P.H., K.H.P.

(*Emergency Public Health Laboratory, Oxford*)

The main purpose of this paper is to report the failure of sulphonamides in the form of lozenges to clear up streptococcal carriers met with during the investigation of outbreaks of streptococcal infection at two residential schools, or to prevent contacts from becoming infected.

School X

This is a residential public school in Wiltshire containing about 200 girls aged 11 to 18, half of whom are housed, during the war, in a large country mansion (B) standing in its own grounds, and half on a country estate (C) about 7 miles away. The girls at C come over each day by motor-bus to B, where the teaching is carried out.

During the last few weeks of the Easter term, 1944, there was a small outbreak of sore throats in B and C; about 12 girls in all were affected. No rashes were observed, but during the holidays one of the girls, Joanna Br., peeled. About ten days after the end of the term one girl—Gillian Bo.—had a typical attack of scarlet fever, and another girl—Gillian Go.—had a sore throat. No bacteriological examinations were made. Joanna Br. returned to school at the beginning of the summer term (April 26), together with her sister, Penelope Br., who was never ill; Gillian Go. returned at the same time, but Gillian Bo. did not come back till May 28.

Six days after the beginning of the term a fresh outbreak of sore throats began, affecting C and later B. Between May 2 and July 14 there were 39 cases. The lesions were more those of a granular pharyngitis than of a follicular tonsillitis. The cases were mild, and none of the girls was seriously ill. On May 25 a girl who had been admitted to the sanatorium on May 8 and returned to school on May 16 was found to be peeling. Up till then no suspicion of scarlet fever had arisen, but on May 25, 26, and 27 three cases of sore throat accompanied by a rash occurred in succession, and it was decided to call in the Emergency Public Health Laboratory at Oxford. A visit was paid to the school on May 29 to take stock of the position and to determine the type of streptococcus responsible for the outbreak. Nose and throat swabs were taken from all girls who had suffered from sore throat in the Easter term, and from all cases and convalescents in the summer term. Two days later—May 31—the entire school, including girls and teaching and domestic staff, was swabbed. The result of these examinations was as follows:

The infecting type of streptococcus was Type 1.

Number of Type 1 carriers among sick and convalescents during summer term	21 out of 33
Carrier rate	64%
Number of Type 1 carriers among normal contacts, including those ill during Easter term	19 out of 164
Carrier rate	11·6%
Number of Type 1 carriers among normal contacts, excluding those who were ill during Easter term	18 out of 156
Carrier rate	11·5%

Origin of Outbreak.—Without going into detail we may say that the summer-term outbreak appeared to be due to infection introduced by one of the girls who had suffered from sore throat or mild scarlet fever at the end of the Easter term or during the holidays. At the first swabbing, on May 29, two of these convalescents (Joanna Br. and Gillian Go.) were still carrying Type 1 streptococci. Joanna Br. had enlarged unhealthy tonsils, the removal of which in June was followed by disappearance of streptococci from her throat. Joanna, however, was housed at B, and was in a junior form, whereas the outbreak started at C among the sixth-form girls. It is improbable, therefore, that she was responsible, though she may possibly have infected her sister, Penelope Br., during the Easter holidays, and Penelope, who was in the sixth form at C, had served as a healthy carrier to introduce the infection. More suspicion attaches to Gillian Go., who was ill during the Easter holidays and who, like Penelope, was in the sixth form and at C. Lack of information, however, on the distribution of streptococci at the beginning of the summer term prevents this conclusion from being more than speculative. Gillian Go. was later seen by an ear-nose-and-throat specialist, who advised removal of her tonsils and draining of her antra—with what effect we were unable to observe.

Treatment at School X

Cases in the sanatorium were given sulphonamide treatment—3 g. of sulphanilamide for three days, followed by 1½ g. a day for one or two further days—and a chlorine gargle. As soon as it was apparent that an outbreak of sore throats was starting, all the girls in the school had their throats treated twice daily with a formol spray, and were given a permanganate gargle—later changed to Milton fluid. The failure of sulphonamide treatment to get rid of streptococci from the throat in these cases was shown by the fact that 9 out of 18 convalescents who were swabbed on May 29 were found to be still carrying Type 1 streptococci; and the failure of the local spray and gargle to protect the healthy contacts was shown by the occurrence of 15 fresh cases of sore throat or scarlet fever among girls who were undergoing this form of preventive treatment.

As soon as the distribution of the infecting organism was known from the swabbings on May 29 and 31, arrangements were made to segregate the heavy carriers in separate dormitories and class-rooms. All girls who developed sore throats were to be treated in the sanatorium for a few days, then kept segregated in special wards at B or C, and not allowed to return to school for 14 days after the beginning of their illness—and then only if they had ceased to be heavy carriers. These measures were put into practice, with apparent success, though it is quite impossible to say how far they were responsible for the results obtained. After June 5, when the heavy carriers were segregated, there was complete freedom for a month, after which three further cases of sore throat occurred—one on July 4 and two on July 14.

An attempt was made to clear up the heavy carriers by local sulphonamide treatment. By the kindness of Messrs. May and Baker Ltd. special lozenges were provided, each containing 1/2 gr. of sulphapyridine and 1/2 gr. of sulphathiazole. Roughly one-third of the carriers were given six of these tablets to suck daily for five days; one-third were kept on a formol throat spray and Milton gargle; and one-third were left untreated. The course of treatment lasted from June 12 to June 17, immediately after which the girls were swabbed. The results were as follows:

Treated with sulphonamide lozenges	8 out of 10 still carrying Type 1 streptococci
Treated with throat spray and gargle	7 „ 12 „ „ „ „
Untreated controls	4 „ 6 „ „ „ „

As the sulphonamide treatment appeared to be without effect, in spite of the fact that the strain was sensitive to sulphonamides, a second course of treatment was given, the number of lozenges being doubled (12 a day) and the treatment maintained for 7 days. Fresh carriers were added to replace those that had become negative. The second course of treatment lasted from June 21 to June 28. Swabs were taken on June 29, with the following results:

Treated with sulphonamide lozenges	10 out of 13 still carrying Type 1 streptococci
Treated with throat spray and gargle	5 „ 12 „ „ „ „
Untreated controls	3 „ 6 „ „ „ „

It seemed evident that neither the sulphonamide lozenges nor the local spray-and-gargle treatment was having any obvious effect on the persistence of streptococci in the throat, and all treatment was therefore stopped. The girls were liberated from segregation as they became negative or ceased to carry profusely.

School Y

This is a small residential preparatory school in Wiltshire containing 54 boys aged 8 to 13. Six cases of scarlet fever occurred between Feb. 18 and 27, 1944. Streptococci of Group A Type 11 were isolated from each of these cases on one or more occasions while they were in Trowbridge Isolation Hospital.

At the request of Dr. C. E. Tangye, County Medical Officer of Health, the Oxford laboratory was asked to investigate the outbreak. A visit was paid to the school on Feb. 26, and again on March 9 and March 28. On each occasion nose and throat swabs were taken from the boys and staff. Excluding the six cases of scarlet fever, 27 of the remaining 48 boys were found on at least one occasion to be carriers of Type 11 streptococci. The results of the individual swabbings were as follows:

Feb. 26: Group A streptococci isolated from 20 out of 47 boys (43%)
March 9: " " " " 13 " 48 " (27%)
(7 of these were previously positive and 6 were fresh carriers)
March 28: Group A streptococci isolated from 8 out of 46 boys (17%)
(7 of these were previously positive and 1 was a fresh carrier)

All strains isolated on Feb. 26 and March 9 were typed, and all, except one on Feb. 26, belonged to Type 11. Tests in the laboratory showed that they were sensitive to sulphonamides. Four out of 17 members of the teaching and domestic staff were also found on Feb. 26 to be carriers of Type 11 streptococci, but were negative on subsequent examinations.

The majority of the carriers yielded heavy or moderately heavy growths of haemolytic streptococci on the first examination, but very light growths at the last swabbing on March 28. Owing to the high proportion of carriers found on Feb. 26, segregation was impracticable. No control measures were taken, apart from those about to be described, which incidentally proved ineffective. No further cases, however, of scarlet fever occurred during the term.

Treatment of Carriers with Sulphonamide Lozenges.—An attempt was made to determine the effect of sulphonamide lozenges on the carrier state. Six lozenges, each containing 1/2 gr. of sulphapyridine and 1/2 gr. of sulphathiazole, were given daily for 6 or 7 days to 12 of the 20 carriers detected on Feb. 26; the remaining 8 carriers served as untreated controls. Treatment lasted from March 1 to March 8. At the subsequent swabbing on March 9 the following results were obtained:

Treated with sulphonamide lozenges .. .. .. 5 out of 12 still carrying Type 11 streptococci
Untreated controls .. .. 4 " 8 " " " "

No obvious effect of the sulphonamide treatment was thus apparent.

Prophylactic Treatment of Healthy Contacts with Sulphonamide Lozenges.—Of the boys who were found on Feb. 26 to be free from streptococcal infection, 24 were given sulphonamide lozenges prophylactically—6 lozenges a day each. Treatment lasted from March 1 to March 8. At the swabbing on March 9 no fewer than 7 of these boys were found to have acquired streptococcal infection during the course of treatment.

Discussion

From the limited observations recorded it seems clear that a prophylactic dose of 6 gr. daily of mixed sulphapyridine and sulphathiazole given in the form of lozenges is unable to protect children from streptococcal infection; and that neither 6 nor 12 gr. daily for 5 to 7 days is able to clear streptococci from the throats of healthy or convalescent carriers. Taken in conjunction with the findings of Kidd (1944), who made similar observations in a boys' school, these conclusions appear to be unavoidable. They receive further support from the recent experience of Hayden and Bigger (1945), who found that the incidence of respiratory disease in an Army unit was apparently unaffected by the prophylactic administration of 5 lozenges a day for 16 days, each lozenge containing 1 gr. of sulphanilamide; and of Wright (1945), whose experience showed that sulphanilamide or sulphathiazole in large doses—46 to 116 gr. daily—was unable to prevent streptococcal cross-infection of children in measles wards. They are, however, at variance with American observations. For example, Watson, Schwentker, Fetherston, and Rothbard (1943) describe how an epidemic of scarlet fever due to Type 19 in a naval station was rapidly brought under control by a dose of 1 g. (15 gr.) of sulphadiazine a day, given either in a single dose or in two divided doses. Though it is not disputed that cases ceased to occur about a month after starting the treatment, examination of the carrier rates provides very little evidence that sulphadiazine had any important effect, either prophylactically or therapeutically, on the frequency of infection. For example, of the two units in the station, in one which was given 1/2 g. of sulphadiazine twice daily for 4 weeks the Type 19 carrier rate fell only from 9.8 to 6%; in the other unit, which was given 1 g. once a day for a fortnight, the Type 19 carrier rate actually increased from 2 to 2.9%.

More recently Holbrook (1944) in the Army and Coburn (1944) in the Navy have described the effect of mass prophylaxis with sulphadiazine, and claim to have achieved a reduction of 50 to 85% in the incidence of streptococcal infections of the respiratory tract by administration of 1/2 to 1 g. (7 to 15 gr.) of this substance daily. No figures on carrier rates are given, but Coburn states that a continuous daily dose of 1/2 g. was sufficient to prevent 85% of the exposed population from becoming infected with haemolytic streptococci.

What is the cause of the discrepancy between the British and the American experience? It may be objected that our observations were on far too small a scale to admit of any reliable deductions being made from the results. Though not denying that our test population was numerically insignificant compared with that of Holbrook or of Coburn, we would point out that our observations were made in residential schools, where the exposure to risk was relatively uniform, and that they were carefully controlled bacteriologically. Under such conditions, we believe that the complete failure of sulphonamides, in a dosage similar to that used by the American workers, to exercise any prophylactic or therapeutic effect cannot be dismissed as unimportant on statistical grounds. The method used by Holbrook and by Coburn—and also by Garson (1943), who reported good results from the prophylactic administration of 4 gr. of sulphanilamide a day in lozenge form—was to treat some units in the Army and the Navy, leaving other units to serve as controls. The wisdom of this procedure seems to us to be questionable. It is impossible at present to foretell how streptococcal infection will develop in any segregated or institutional population, even when the distribution of infection has been carefully mapped out by bacteriological means beforehand. Experience of several outbreaks investigated by the Oxford laboratory has shown that a low carrier rate may be followed by numerous cases, and a high carrier rate by few. Similar observations have been made by Hamburger (1944) in the spread of streptococcal infection in American army hospital wards. It is therefore hazardous to draw conclusions from the behaviour of an infection in different units. Even in similar populations of mice, all infected with *Bact. typhi-murium* in the same way at the same time, Topley and his colleagues (1928) found that the mortality rate and average survival time might vary considerably. Instead of treating all men in alternate units, it would be more satisfactory to treat alternate men in the same units. That is what Hayden and Bigger (1945) did in their trials of prophylactic sulphanilamide treatment in the British Army. The negative results that they obtained are all the more significant.

Our conclusion, therefore, is that a case has not yet been made out for mass prophylactic treatment of populations exposed to streptococcal infection; and that before such a method, attended by disadvantages and dangers that it is unnecessary to discuss here, is adopted as a routine in the fighting Forces or for the civilians of this country, further trials should be made under adequately controlled and statistically satisfactory conditions.

One other point requires discussion. Special virtue has been claimed for local sulphonamide therapy to the throat in the form of either sprays or lozenges (Arnett *et al.*, 1943; Garson, 1943; Freis, 1944). We have had little experience of sprays, but the combined observations of Kidd (1944), of Hayden and Bigger (1945), and of ourselves seem to show that, so far as the prevention or cure of streptococcal infection is concerned, sulphonamides given in the form of lozenges in a total dose of 7 to 15 gr. (1/2 to 1 g.) a day have little or no effect. Puzzling over the reason for this failure, we were prompted by a suggestion of Dr. Calman, in our laboratory, to find out how closely the contents of a lozenge came into contact with the throat and posterior wall of the pharynx. For this purpose 22 of our laboratory staff sucked a pill containing 2 gr. of methylene blue for about 5 minutes, swallowing the saliva at intervals. Their throats were then carefully inspected in good daylight. The results were striking. Though the lips, tongue, mouth, hard palate, uvula, and anterior pillars of the fauces were stained deep blue, either no blue at all or, more frequently (16 out of 22 subjects), a slight coloration only, could be detected on the tonsils—usually confined to a small area at the top in between the angle formed by the anterior and posterior pillars of the fauces. Except in two instances, in which there was a very faint streak on each side of the midline, no blue coloration at all could be detected on the posterior wall of the pharynx. Subsequently it was found that Arnett (1943) had carried out a similar experiment using chewing-gum impregnated with gentian violet or methylene blue, and, like us, had observed little or no staining of the tonsils or posterior pharynx if the subject chewed his gum in the upright posture; some staining, however, usually occurred if the recumbent position was adopted.

Thinking that our results might have been different if our subjects had not had healthy throats, we made observations on 6 patients in the isolation hospital who were suffering from measles or scarlet fever and whose tonsils were greatly enlarged. The pills were sucked in a semi-recumbent position, which, in view of Arnett's findings, may have affected the result. In one patient the whole of the medial surface of the tonsils was stained light green; in the remaining five the coloration was slight and was restricted to a small triangle at the top. In no instance was any coloration of the posterior pharyngeal wall seen.

These findings are in accordance with the observations of Bloomfield (1922), who concluded from an extensive series of experiments that there is a highly efficient mechanism, apparently dependent on suction currents, by which any bacteria introduced into the mouth are drawn directly backwards towards the oesophagus, avoiding the tonsils and posterior wall of the pharynx. It follows, therefore, that drugs given in the form of lozenges or chewing-gum can have little or no local effect on the throats of persons in the upright or sitting position unless they are sucked almost continuously throughout the day and night, as in MacGregor and Long's (1944) observations on penicillin pastilles. They are therefore unlikely to be of much value for prophylactic purposes in the ordinary healthy contact.

Summary and Conclusions

An outbreak of scarlet fever due to *Str. pyogenes* Type 11 in a residential preparatory school for boys, and an outbreak of sore throat accompanied by cases of scarlet fever due to Type 1 in a residential public school for girls, are briefly described.

Treatment of healthy and of convalescent carriers with 6 to 12 lozenges a day for 5 to 7 days, each lozenge containing 1/2 gr. of sulphapyridine and 1/2 gr. of sulphathiazole, had no apparent effect, as compared with control carriers receiving either a formol spray and hypochlorite gargle or no treatment at all, in clearing the infecting type of streptococcus from the throat.

Prophylactic treatment of healthy non-infected contacts with 6 lozenges a day had no apparent effect in preventing streptococcal infection of the throat.

Observations made on persons sucking methylene-blue tablets showed that only a fraction of the dye was deposited on the tonsils and none on the posterior pharyngeal wall; and it is therefore concluded that neither for the prophylaxis nor for the cure of streptococcal infection of the throat are lozenges containing sulphonamide drugs likely to be of value in practice.

It is maintained not that prophylactic sulphonamide treatment of streptococcal infections is useless but that further carefully controlled investigations should be carried out before this method, which is now being extensively used in the American Forces, is applied to the civilian or Service personnel of this country.

Our thanks are due to the medical officer of the girls' school, and to the head master of the boys' school, for their help in enabling us to carry out these investigations; and to Dr. Nora Archer, superintendent of the City Isolation Hospital, Oxford, for allowing us to make observations on patients with enlarged tonsils.

Major, R.A.M.C.

This paper includes a report of a series of missile wounds of the abdomen treated in the forward areas during the present campaign in Europe. In 200 consecutive battle casualties the abdomen was explored in 56 cases, so that a little over a quarter of the work of the forward surgeon is likely to be concerned with this type of injury. No selection whatsoever has been exercised in the choice of patient, and with one exception every case seen in the pre-operative ward and diagnosed as an intra-abdominal lesion has been operated upon. This one patient was so severely injured that in spite of suitable resuscitative measures he collapsed after the administration of 0.1 g. of pentothal, and it was considered useless to continue. Every patient is now given his chance, because it has been found that what may well be considered a hopeless case sometimes confounds such an opinion.

The mortality rate in this series is therefore a fair representation of that occurring among all patients with abdominal injuries who arrive at the forward surgical centre working within a few miles of the fighting-line. There is probably a small additional mortality at the base hospitals, due to subsequent complications, but when evacuated down the line after anything up to three weeks the patients have been in good condition.

All save one of our cases have been operated on under pentothal anaesthesia alone, the exception receiving in addition a spinal analgesic. For the success of this somewhat exacting type of work under difficult circumstances the choice of the anaesthetist is equally as important as the choice of the surgeon. The forward anaesthetist should be the most skilled and experienced available, for the type of case with which he has to deal is the most difficult of all to anaesthetize. In view of forthcoming campaigns in other parts of the globe, no apology is necessary in pleading that wherever a forward surgeon is sent he should be accompanied by a high-grade anaesthetist if his work is to be a success and not marred by anaesthetic mortality.

Diagnosis

The diagnosis of the straightforward abdominal case is easy; that of the dubious one extremely difficult—so much so that some cases will always provide such an element of doubt that an occasional negative laparotomy will be undertaken. The reduction of this number to a minimum is, however, of paramount importance, because, as so many of these cases have other and severe lesions, such a laparotomy lessens their chances of recovery. Especially is this so in chest injuries, which may closely simulate an intra-abdominal lesion. Let it be said that there is no one symptom or sign that is always present, no one single observation upon which reliance can always be placed, and a diagnosis must be made by a summation of the points in favour and the points against.

A high proportion of cases in which a hollow viscus is injured give a history of early vomiting, repeated at intervals. This is not like the vomiting of a severely shocked patient, which occurs often after the administration of the traditional cup of hot sweet tea, which few of them can assimilate, or during the period of their recovery from the shock. This vomiting in those injured in the abdomen occurs when shock is absent and when nothing has been taken by the mouth.

The site of the wound should be located, and any injury to the anterior or lateral abdominal wall must be considered to be perforating until proved otherwise. If evidence from other signs and symptoms is not conclusive, all such wounds must be explored and followed to the end of their course before deciding that the peritoneum is not perforated. It is quite useless to probe the wound, as the track is often obscured by the natural elasticity of the tissues, and exploration must be by careful dissection. No attention must be paid to the size of the skin wound. We have seen a through-and-through injury of the stomach in which the entry in the skin was pin-head in size.

Wounds of the buttocks and flanks must always be suspect, and a thorough abdominal examination carried out in all cases. But intra-abdominal lesions may be caused by missiles entering high up in the chest or low down in the thigh. Where a rectal injury is suspected or possible a finger examination must be carried out.

In examining the abdomen it should not be forgotten that many of these patients are admitted heavily morphinized and that the classical sign of an abdominal catastrophe will be obscured or even absent. In one case, for example, no local tenderness, guarding, or rigidity was present whatsoever. On the other hand, certain extra-abdominal lesions will give rise to signs simulating an intraperitoneal viscus injury, particularly in perforating wounds of the lower chest, in which it is essential to establish a correct diagnosis. Unnecessary laparotomy may very well just turn the scales against recovery.

Injuries involving considerable damage to the abdominal musculature will naturally give rise to tenderness and rigidity, as will also lesions in which the kidney is affected. But in such cases, although the abdomen is held in apparent guarding, it is sometimes possible, in between the rapid respiratory excursions, to palpate muscular relaxation. This is never possible when true rigidity, the result of an intra-abdominal lesion, exists. It is maintained throughout the periods of respiration.

In spite of the sometimes dubious findings, full abdominal examination is of the highest importance, not only in determining a diagnosis but also as an indication of the best approach that can be made to deal with the condition. Auscultation of the abdomen must never be omitted, and we regard the information thus obtained as of the greatest importance. In the examination of a large number of patients suffering from wounds other than those involving the abdomen we have found that peristaltic sounds of the character heard in a normal man are usually present. In most of the cases in which there is a lesion of the bowel the sounds have been completely absent or reduced to such an extent that a long wait is necessary before a characteristic tinkle can be heard. Where a solid viscus is injured or where intraperitoneal bleeding alone is taking place, peristalsis in the early stages is present, though markedly reduced, before finally disappearing altogether.

In cases in which a retroperitoneal haematoma exists peristalsis is also reduced, and in the later stages when ileus sets in is absent altogether. Operation in these cases is contraindicated, and a differential diagnosis between such an injury and an intraperitoneal haemorrhage has to be established by consideration of the other diagnostic features. In the case of the latter injury, abdominal tenderness and shock are usually far greater. Location of the foreign body by radiographs is a valuable adjuvant in cases such as this, because an indication is given of what structures are likely to be damaged by the missile between the entrance wound and its final position.

Resuscitation

Not all cases of intraperitoneal injury need resuscitatory methods. The amount of transfusion required to render the patient fit for operation must vary according to the severity of the local as well as of the associated injuries. One patient, with a severe fracture of the femur running into the knee-joint in addition to the abdominal lesion, required 7 pints of blood before he was in any shape for operation. We have, however, aimed at improving the blood pressure to a minimum of 60 mm. diastolic and 100 mm. systolic. The mortality in cases presenting less than these figures has been high, although successes can be recorded among this group. Particularly is this so in patients in whom the injury has produced a large evisceration of the gut. Such patients do not respond well to resuscitation, but improve immediately the bowel is returned into the abdomen.

Pre-operative transfusion with whole blood was used in the majority of cases. A transfusion with either plasma or blood was invariably given during operation.

Anaesthesia

Sodium Pentothal.—Except in one case it was decided to use pentothal as the sole anaesthetic, not because it was believed in the beginning to be the best, but because it was the best drug available under the field conditions. The other drugs supplied were ether and chloroform, and (for spinal analgesia) stovaine 5% and light nupercaine.

Ether.—While ether causes little damage to healthy tissues and is rapidly excreted, it might well do considerable harm to tissues suffering from anoxaemia due to haemorrhage and shock, and its excretion is certainly prolonged where there is a much diminished circulatory volume.

Chloroform.—All that has been said of ether is applicable to chloroform, only to a greater degree, except that it is also harmful to healthy tissues.

Spinal Analgesia.—Enough has already been written by others on its dangers in severely shocked patients; it was used in one case, and will be referred to later, together with the reason for its use.

Splanchnic Analgesia.—This is ideal in cases of shock, but takes too long to administer to be considered under the conditions which pertained. The method to be described was first used by one of us (A. F. A.) in the Western Desert Winter Campaign, 1941-2 (7 cases), and again in Normandy, June, 1944 (5 cases).

Pre-operative Drugs.—As all the patients had had morphine at some time or times between their being wounded and their arriving at the surgical centre, and as it was often impossible to find out even approximately how much they had been given, they received no further drugs, sedative or otherwise, before operation.

Pre-operative Method

A 5% solution of pentothal was used, and, provided no crystallization had occurred, three-day-old solutions were found to be as efficacious as those that had been recently prepared. The solution should be kept in an air-tight container.

An estimate of the patient's condition was made, based chiefly on the diastolic blood pressure: as this decreased so the degree of shock was found to have increased. A diastolic pressure of below 70 mm. Hg meant that at least a moderate degree of shock was present; to patients with diastolic pressure at these levels it was found unnecessary, and indeed dangerous, to give more than from 0.1 to 0.25 g. as an initial dose; this was usually found sufficient to enable the patient to have his clothes removed, his abdomen washed, to be shaved, and to be catheterized. If a greater amount was needed, not more than 0.2 g. was given at a time, and a waiting period of at least two minutes was observed between doses in order to watch its effect. Of course, for slightly shocked patients far greater doses were required, and these could be given safely; to these patients as much as 1 g. often had to be given for the preparations described.

After sufficient relaxation had been obtained for the peritoneum to be opened it was found that this relaxation was maintained for long periods—in some cases up to one hour—without further doses being required, although the conjunctival and cough reflexes were present. Sometimes small doses had to be given during the operation, and most cases had a further small dose immediately before closure of the peritoneum. As there was always a transfusion in progress during the operation, the pentothal was injected into the rubber tubing 1 in. to 3 in. from the transfusion needle.

No artificial airway was used unless there was respiratory obstruction, as this caused coughing in patients lightly anaesthetized. If one were necessary, either a nasopharyngeal tube or a Magill's endotracheal tube was passed.

Difficulties Arising during Operation

Respiratory Depression.—Early in the series there were several cases in which this happened to a severe degree. They were all cases in which more than 0.2 g. had been given as a single dose in a matter of seconds. After these had occurred not more than 0.2 g. was given to patients suffering from more than slight shock without waiting at least two minutes to observe its effect, and no more trouble in this respect was experienced. These cases were dealt with by passing a Magill's endotracheal tube and inflating the lungs with oxygen or air. There were no untoward consequences.

Vomiting.—This occurred occasionally, and, when it did, always in the period of preparation while the patient was lightly anaesthetized. A stomach-tube was then passed: this caused a temporary deterioration in the patient's condition, but recovery took place within a short time of the finish of the procedure. Regurgitation of fluid at any time during the operation without any effort being made by the patient happened in a few cases; this was dealt with by swabbing out the pharynx and passing a large (size 10) Magill's endotracheal tube.

Hiccup.—This came on only in cases that required large doses of pentothal—i.e., in the neighbourhood of 2 g. in the first three-quarters of an hour and after the peritoneum had been opened. While the patient did not suffer the surgeon sometimes did, as it was inconvenient, when attempting to control bleeding in the renal or splenic pedicle, to have the diaphragm making spasmodic descents. This could be stopped in a few minutes by rebreathing oxygen without carbon dioxide absorption.

Post-operative Drugs

None were given unless the patient was restless, in which case morphine 1/6 gr. was administered intravenously—by this method because it was found that with established shock of any severity it was quite evident that, given by any other route, it was absorbed so slowly as to be of little use. To illustrate this, one case was, unknown to us, given morphine 1/2 gr., in two doses of 1/4 gr., within 4 hours, on account of restlessness. It had no effect whatsoever. Now, this patient was practically pulseless when he left the theatre, and although he regained full consciousness he remained in an extreme state of shock until he died 48 hours later. It was quite evident that the morphine had not been taken into the circulation.

Post-operative Complications

Vomiting.—This occurred in one patient only. In this case vomiting took place four times in the 12 hours immediately after operation, and then ceased.

Pulmonary.—There was one case of bilateral basal collapse, which made a complete recovery, and three cases of unilateral pneumonia involving the bases only, one of them ending fatally. This patient had suffered from severe exposure, including immersion in the Rhine, after being wounded.

Deaths.—Out of 21 deaths, in 6 only could the anaesthetic be held to have played any part; of these 6, 5 did not regain consciousness, and 1, already referred to, developed pneumonia. The 5 patients were all severely wounded men, 1 with severe additional injuries and 2 with peritonitis. One patient would undoubtedly have recovered consciousness except for the occurrence of a volvulus after operation.

Discussion on Anaesthesia

With this form of anaesthesia no great improvement in the ultimate recovery rate of perforating wounds of the abdomen can be claimed, but at least the mortality is no greater than with other forms. There are many advantages, such as: an abdominal relaxation equal to that obtained with spinal analgesia; an almost complete absence of post-operative vomiting, which makes the work of a hard-pressed nursing staff during a battle considerably lighter; and a generally quiet recovery period in which the discomforts of the patient are not added to by the toxic effects of the anaesthetic. Chest complications are not prominent, and are certainly not more than is to be expected in a series of severe upper abdominal operations.

In the case requiring large doses of pentothal—that is, in the case suffering little from shock—there is only a small margin between the levels of anaesthesia when the patient is sufficiently anaesthetized and when respiration ceases. Also, it is in these cases that hiccup is prone to occur; for this type spinal analgesia is recommended. It is of advantage to have the patient breathing oxygen in a closed circuit with carbon dioxide absorption; then if an overdose is inadvertently given it is a simple matter to keep respiration going by squeezing the rebreathing bag until physiological respiration is resumed. It is safest, however, to follow the method advised and to give small doses, repeated when required.

There are no cardiac disturbances, and such falls in blood pressure as occur can always be accounted for by the duration and severity of the operation. In one patient the blood pressure actually rose from 120/50 before to 132/78 after operation. Although in this series large doses of a barbiturate were being given there were no mental disturbances. One patient was unconscious for 12 hours; the remainder regained full consciousness within 6 hours.

It was indicative of extreme shock if the patient required 0.25 g. or less during the period of preparation, usually lasting 10 to 15 minutes, and those patients requiring 1 g. or less for the whole operation, including the preparatory period, stood a very poor chance of survival—one patient out of eight surviving.

Operative Procedure

Catheterization before the operation is begun is essential, as not only does this eliminate a possible mechanical obstruction but it will sometimes reveal unexpected renal damage. Preoperative stomach intubation has been limited to those cases in which vomiting has been marked and profuse, and, where necessary, it is now carried out under the initial stages of the anaesthetic.

With few exceptions a median or paramedian incision has been used, the site of choice being that on which it is thought maximum injury to the abdominal structures is present. Where the abdominal wall has been grossly injured, operation has been carried out through the existing wound, after its excision and, if necessary, enlargement.

In a thoraco-abdominal wound a decision has to be made as to whether the approach shall be through the diaphragm or by an abdominal incision. Where it has been decided during the diagnosis—in which radiographs are extremely valuable—that the damage is confined to structures easily approachable through the diaphragm, then this is the preferable route. Otherwise an alternative approach must be employed. It is only in wounds of the lower chest wall that the former approach is likely to be used, and it seems unnecessary to resect a rib, sufficient exposure being obtained by suitable retractors after an intercostal incision which excises the wound of entry. It should be noted in passing that splenectomy, through this approach, is a much simplified and more rapidly performed operation than through an abdominal incision.

In many cases the abdomen is filled with blood, which should be sucked and swabbed away before proceeding to a full inspection of the abdominal contents. This must be carried out in all cases save those in which the approach has been through the diaphragm and the surgeon is certain of the location of the injured structures. In some of our cases unexpected injury of the jejunum has been located when the main lesion has been far away in the right iliac fossa.

Some definite plan must be carried out in the examination of the abdomen; we have, as an initial stage, adopted the procedure of inspecting the region believed to have been damaged, and after dealing with the injury there, the remaining contents—the small intestine from the caecum to the duodenum, the large bowel from the transverse colon, down on either side—are searched. Criticism may be levelled at dealing with soiled gut first, in that spread of infection is likely, but against this may be placed the fact that if a perforation is not sealed at an early stage in the operation the actual manipulations of the gut encourage extensive leakage through the site of injury.

No intraperitoneal medication has been used in the series of cases reported, but we believe that microcrystalline sulphadiazine is of value. It is probably best to leave a small catheter protruding from the peritoneal cavity, and through this to instil 5 g. of the drug in suspension at 8-hourly intervals for 24 hours. To prevent leakage the tube is clipped at the end of each instillation.

Drainage of the general peritoneal cavity has been used only in cases of gross liver damage or those in which frankly infected peritoneal exudate was present.

Individual Injuries

1. Stomach

Little need be said about these except to remark that wherever the anterior stomach wall has been perforated it is essential to open the lesser sac of peritoneum in order that the posterior wall may be examined.

2. Duodenum

Large wounds of the duodenum have a marked tendency to break down and to give rise to a duodenal fistula, from which the patient will ultimately die. In addition to suture of any large rent, a gastro-enterostomy, performed at the time of the initial operation, is probably advisable. Drainage down to the site of the lesion should be instituted.

3. Small Intestine

It is often stated that the whole of the intestine should be examined before a decision is made whether resection or suture is to be carried out. This in practice is not satisfactory, as it is impossible, with multiple perforations, to prevent leakage from these while the rest of the bowel is examined. Unless, as the peritoneum is opened and the examination of the abdominal contents has begun, it is quite obvious that resection will be necessary, perforations should be treated as they present, either by invagination or by one or two through-and-through sutures.

Occasionally it will be necessary to resect a section of the bowel, and some of these repaired perforations may be included in the length of gut removed. Even so, the short period of time spent in the repair has not been wasted, as it has prevented the escape of intestinal contents and consequent soiling.

Resection should be carried out only in those cases in which the mesentery is so damaged as to interfere with the viability of the gut, or in injuries the local repair of which is likely to be followed by stenosis of the intestinal lumen. In our series, resection was carried out as the only intra-abdominal operation in 3 cases, of which two recovered, and, in addition to other procedures, on a further 3, two of which terminated fatally. Post-operative convalescence in these cases has caused little more anxiety than in those in which the lesion has been oversewn. The fatal results occurred in patients with severe associated lesions who were in extremely poor condition before operation. End-to-end anastomosis has been employed, the bowel being severed somewhat obliquely in order to give a larger lumen after suture.

4. Caecum

When the lesion is small and on the peritoneal surface it is perfectly safe to oversew or invaginate the perforation, but when the rent is large and the caecal wall grossly bruised, exteriorization with partial repair to form a caecostomy is advisable. In cases in which the posterior wall, uncovered by peritoneum, is injured, the surface should be exteriorized and the rent left open or sutured, according to the severity of the wound. The caecum will be brought out through a separate muscle splitting or dividing incision.

5. The Large Bowel, excluding the Rectum

The general principle of mobilization and exteriorization of the injured viscus is one that must dominate treatment; but before such procedure is carried out the perforations in the bowel should be temporarily sutured to prevent escape of faeces during the manipulations.

In the case of the transverse or pelvic colon exteriorization is simple, and rarely is mobilization necessary, but in other parts of the large bowel not provided with a mesentery the procedure is more difficult. In a case of injury to the upper part of the ascending colon the whole of the bowel from the caecum to the hepatic flexure may require freeing if the bowel is to be brought to the surface without tension. The peritoneum along the outer border of the bowel is incised, after which the latter is gently stripped of its attachments to the posterior abdominal wall, until it is held only by the thin layer of tissue containing the blood supply. Gauze dissection is of great value in this manœuvre. Some cases with a loose posterior attachment will free easily, but when the bowel is fixed fairly firmly, and the patient is broad and muscular, every possible band of tissue attachment has to be divided to obtain the necessary mobilization. A similar procedure is necessary for lesions of the descending colon, the injured bowel being brought out through a separate incision in the loin.

The type of colostomy performed is a matter of choice. Where it is possible, the ascending and descending links may be sutured together along the lines of a Paul–Mikulicz operation, the damaged portion of the bowel being subsequently cut away. An enterotome is used at a later stage to crush the spur intervening between the two loops of gut. It is, however, a procedure that is not always possible save in the case of the transverse and pelvic colons, and, where feasible, requires more extensive mobilization, the opening up of larger cellular spaces from which toxic absorption may occur, and additional time. We have not employed this technique, and have always exteriorized the bowel as a spur colostomy, using the method described by Ernest Miles. This is a matter of personal choice; but as a result of experience in civilian life and in periods spent at base hospitals we have found that the closure of such a colostomy is not a difficult procedure, and, provided that care is taken not to open the peritoneum, is unaccompanied by danger.

The argument advanced in favour of the exteriorization of all large-bowel wounds is that there is usually an associated bruising of the wall surrounding the actual perforation, and that any suture line is most likely to give way. This is undoubtedly true in most cases, especially when extensive faecal soiling is present. But it can never be denied that a colostomy, however temporary, is but a source of discomfort to the patient, particularly in the ascending colon; where the faecal discharge is fluid. If it can be avoided with safety a service has been done to the patient.

Occasionally the wound in the colon is small, and so clean-cut and without surrounding tissue damage that simple suture may be carried out, or the perforation sutured and extraperitonized by stitching the peritoneum and the rectus sheath to the bowel wall around the injury. This advocacy of any procedure other than exteriorization may be considered dangerous, but with prolonged experience of abdominal injuries selected cases can be treated safely in this fashion. Where the ascending colon has been exteriorized a short-circuit anastomosis between the small intestine and the transverse colon is of value in reducing the fluid faecal loss to a minimum.

In two of the cases in our series such extensive disruption of the colon was present as to necessitate resection with subsequent anastomosis. Both patients died, one after 16 days. This case was associated with a large injury of the duodenum, for which gastro-enterostomy was performed 14 days after the injury. At the time of the second operation the anastomosis was observed to be firmly healed.

6. The Rectum

Where the lesion is intraperitoneal, repair and colostomy should be carried out. If the rupture is small and below the peritoneal reflection, divergence of the faecal flow by a colostomy is probably sufficient; but in cases in which the damage is severe, drainage of the pelvic faecal tissues is necessary, after removal of the coccyx and strapping up the rectum.

7. Solid Viscus Injuries

Wounds of the kidney may be present with other intra-abdominal lesions; when the organ is grossly disrupted, nephrectomy, through the abdominal route, must be carried out. Two cases in our series have been associated with such injuries; both terminated fatally.

Splenectomy

When any but the slightest damage has been suffered by the spleen, splenectomy is the correct treatment to adopt. We had three such cases; in two of them—in which injury to the viscus was the only damage—recovery resulted. The liver was damaged in only one case in this series, the rent being oversewn. This procedure is impossible when the injury is gross, or if it involves the diaphragmatic surface of the viscus and an abdominal approach has been made. Reliance must then be placed on packing, this being removed in 48 hours. When the injury is extensive and there is likely to be a considerable escape of bile, drainage of the area is desirable.

If, on the diagnostic points to which reference has been made, it can be assumed that the injury is likely to be on the diaphragmatic surface, approach through the chest is indicated.

Post-operative Care

Considerable controversy has arisen as to whether these patients should be nursed lying flat or in the typical Fowler position. Our own opinion is that, provided the patient is not sat up until his shock and its effects upon the circulation have disappeared, there is nothing to choose between these alternatives. Some patients who have been nursed lying down have begged to be allowed to sit up; some sitting up have asked to lie down. It is the contrariness of human nature, as we do not believe that ultimate recovery or otherwise is affected thereby.

Gastric suction is instituted as soon as the patient recovers consciousness, the Ryle tube being passed through the nasal route. It is retained until only bile is being drained from the stomach, and during this time fluids are allowed by mouth. So long as stomach suction is maintained—in the average case for from 3 to 4 days—four pints of saline and one of plasma are given by intravenous drip daily. Rarely, when suction has to be continued beyond this period in patients in whom the large bowel is not involved, saline may be administered through the rectal route. Provided a narrow catheter is used, and provided the flow is intermittent—a half-hour in every hour—absorption by this method is satisfactory. From time to time, after suction has ceased, the patient again starts to vomit, and there must then be no hesitation in resuming this and the saline drip.

Any severe ileus is rare in cases so treated, but in the event of abdominal distension becoming increasingly great, intravenous pituitrin—1 c.cm. in 10 c.cm. of water or saline—is of the utmost value, and the passage of flatus and faeces is immediate.

As soon as stomach suction is stopped the diet may rapidly be built up, the inclinations of the patient being largely followed. An enema or colostomy wash-out is useful when the bowels fail to act normally. Sulphaguanidine is valuable in reducing the offensiveness of colostomy.

A course of penicillin is now given as a routine, either by periodic injections or by a continuous intramuscular drip, as not only is the drug of value in counteracting the sepsis of the actual wound, but it has been found that staphylococci and streptococci are normal contaminants of the peritoneum in such cases. Those associated with grossly dirty wounds have been given sulphadiazine in the intravenous drip. In such cases alkali has always been administered by the same route.

Factors in the Causation of Death.—First and foremost in the causation of death, as in all civilian types of abdominal catastrophe, is the period of time elapsing between the onset of the lesion and the start of the operation; the accompanying Table illustrates this point. It will be seen that among all cases coming to operation within 10 hours of the receipt of the injury the mortality is 20%, rising to 71% in those arriving after 20 hours.

Table showing Relation of Time of Wounding to Mortality Rate (54 Cases)

Time Factor	No. of Cases	No. of Deaths	Mortality (%)
Within 10 hours	30	6	20
„ 20 „	17	10	49
Over 20 „	7	5	71

Coupled with this factor is the severity or otherwise of the lesion and associated extra-abdominal injuries. Of the six cases culminating fatally in the first group, five had gross and multiple injuries either inside the abdomen or associated with that lesion, and all died within 36 hours. The sixth patient died after operation for a post-operative obstruction.

Summary and Conclusions

The treatment of gunshot wounds of the abdomen is discussed.

The use and advantages of pentothal anaesthesia in these cases are brought forward.

Pentothal has been found to be an ideal anaesthetic for abdominal surgery in shocked patients.

While this drug can be used with safety where there is only a mild degree of shock and where large doses have to be given, it is difficult of control and cannot be recommended in these cases.

The York Clinic at Guy's Hospital is the first psychiatric in-patient clinic to be established in this country as part of a general hospital in close association with the tradition of general medicine. It was not expected to be able to admit psychiatric patients till after the war, but the foresight of the York Council in proceeding with the building was justified, for at the end of 1943 the opening of the clinic for the purpose for which it was built was urgently requested by the Ministry of Health to provide beds for psychiatric casualties among officers of the Services. An immense amount of work had to be done by Dr. R. D. Gillespie (now Air Commodore, R.A.F.) and Mr. Lees Read to furnish and equip the clinic and prepare the organization. It opened on April 3, 1944, and a report on the first year's work has been issued as a cyclostyled document of six foolscap pages by the acting medical director, Dr. Felix W. Brown. There is undoubtedly a growing demand for treatment by modern psychiatric methods outside a mental hospital, and the York Clinic at Guy's has excellent opportunities to provide the right kind of training for future psychiatrists.

THE BACTERIOLOGICAL EXAMINATION OF INFECTED DENTAL PULP CANALS AND USE OF PENICILLIN IN PULP-CANAL THERAPY

BY

FREDERICK E. SHAW, L.D.S.R.C.S.
London Hospital Medical College and Dental School Research Scholar

EVELYN SPRAWSON, M.C., D.Sc., M.R.C.S., L.D.S.
Professor of Dental Surgery, London Hospital Dental School

AND

H. B. MAY, M.B., M.R.C.P.
Assistant Director, Clinical Laboratory, London Hospital

It has been shown by Bulleid (1938) and others that the commonest organism causing an infection of the pulp canal and periapical tissues is *Str. viridans.* Most strains of this organism are resistant to sulphonamides, especially in the presence of pus, but Fleming (1929) found that many are very sensitive to the action of penicillin, and therefore the effect of this chemotherapeutic agent on infected pulp canals seemed worthy of investigation.

Adams (1944) injected penicillin through the apical foramina in 2-c.cm. quantities, using 2,000 or 3,000 units for each injection. It is difficult to see how the periapical tissues could absorb this volume of fluid, and his criteria of sterility were not given; apparently an insufficient number of consecutive sterility results were accepted as adequate. He obtained a satisfactory result in all of 12 cases which he treated. It is surprising that in every case he apparently assumed that he was dealing with organisms sensitive to penicillin, although sensitivity tests were not carried out. In view of this work it was necessary to repeat the use of penicillin with more adequate bacteriological control.

It was clear that the common methods used in assessing the sterility of pulp canals—namely, (*a*) the absence of clinical signs of periodontitis, and (*b*) that the dressings removed appear clean and odourless—were inadequate for this work. Grossman (1936) showed that of 150 teeth, which by the appearance of the canal and odour of the dressing were judged by several dental practitioners to be ready for filling, 42% were still infected. A putrid odour may be produced by some organisms, especially anaerobic bacteria, but is often absent even in cases of gross infection by aerobic bacteria. A smear of the necrotic contents of the pulp canal, as suggested by Grossman (1940), is a very crude test of sterility. Radiographs of the periapical tissues may or may not reveal the presence of a rarefying osteitis due to infection, but this rarefaction must necessarily continue for some time even if the tissues have been rendered sterile; thus radiographic evidence is of little value. The only methods of ascertaining whether sterility has been achieved that are capable of withstanding criticism by bacteriologists are cultural methods, and the technique should be one which will demonstrate the relative number of organisms and the presence of anaerobic as well as aerobic organisms, and must entail no extra effort or skill on the part of the dental surgeon.

The ability to sterilize the pulp canal and periapical tissues has long been disputed. Gottlieb *et al.* (1938), Thoma (1943), and Grossman (1940) state that these tissues can be sterilized; and Sprawson (1926) concludes that "when tested by cultures and films they can usually, after prolonged treatment, be rendered sterile," but he found that six months or more was necessary to obtain sterility in some cases. Prinz (1911), Bulleid (1938), and others have stated that no antiseptic treatment will permanently sterilize a once-infected pulp canal. It is doubtful, however, if the bacteriological technique employed in all past work has been adequate to enable a final conclusion to be drawn.

Penicillin is a freely diffusible substance, and it was hoped that it would diffuse into the periapical tissues and increase their chance of permanent sterility.

Method

The following procedure was adopted for the bacteriological investigation of infected pulp canals and their treatment with penicillin. Single-rooted teeth only were investigated. On the first visit a radiograph was obtained and the tooth isolated with a rubber dam, the crown being repeatedly swabbed with 70% alcohol. The pulp canal was opened with a sterile rose-head bur in the usual way, from the palatal aspect. The tip half of a sterile paper point moistened with nutrient broth was introduced into the canal and then dropped into a sterile test-tube. A second paper point was then introduced into the canal and dropped into 10 c.cm. of sterile broth. Having thus obtained material for the bacteriological investigation, the pulp canal was cleared mechanically with sterile instruments and reamed to a satisfactory size.

Penicillin was introduced into the pulp canal by saturating sterile absorbent paper points in a solution containing 20,000 Oxford units per c.cm. It was found that, on an average, approximately 50 units of penicillin was introduced with each dressing, which was sealed by a layer of sterile wax, followed by zinc oxyphosphate cement, wax being used to prevent any destruction of penicillin by the cement (zinc oxide with eugenol was observed to destroy penicillin completely); and the above procedure was repeated, usually at 48-hour intervals for the second and subsequent visits, if the organisms were found sensitive to penicillin, otherwise a tricresol dressing was substituted.

The sterile test-tube containing a paper point and the second test-tube with a point in broth were sent to the laboratory, where the following investigations were made.

The first point was withdrawn with sterile forceps and rubbed over a blood-agar plate while a sterile iron strip was introduced into the tube of broth to provide conditions in which both aerobic and anaerobic organisms will grow, cultures being incubated at 37° C. overnight. The direct plating gives a rough quantitative result of the organisms present, while the broth is a more sensitive test for both aerobic and anaerobic organisms—growth of the latter being possible in the presence of the metal strip. Subcultures were made from the broth aerobically and anaerobically to confirm sterility and to carry out penicillin-sensitivity tests on organisms grown.

Results

A case was not considered sterile until a minimum of three consecutive sterile results were obtained; in some cases up to seven consecutive sterile results at 48-hour intervals were obtained, while in others, as a more stringent test of sterility, a sterile point was sealed in the pulp canal for a week and used to inoculate a tube of broth.

Twenty-three cases were treated; with 3 of these no organisms were cultured, and the condition was possibly the result of aseptic gangrene of the pulp. The remaining 20 cases comprised 16 with chronic periapical osteitis, 3 with an acute suppurative inflammatory process superimposed on the latter, and 1 with an acute periodontitis resulting from gangrene of the pulp.

The following organisms were grown from the original paper points in the 20 cases examined: *Str. viridans* (17); non-haemolytic streptococcus (3); beta-haemolytic streptococcus (2); anaerobic streptococcus (1); *Staph. pyogenes* (2); *Staph. albus* (1); *Bact. coli* (3); *B. subtilis* (2); *Ps. pyocyanea* (2), and *Saccharomyces* (1).

It should be noted that in 11 cases a mixture of two organisms was grown: of course, in these cases the infection of the periapical tissue might well have been caused by a single organism, the secondary infection of this tissue depending on the relative invasiveness of the bacteria in the pulp canal.

Individual insensitive strains are often found in groups of organisms which are in general sensitive, and sensitive strains are known to become insensitive when the dosage of penicillin is small. Although the latter point was not observed, in 3 out of 17 cases the original culture of *Str. viridans* proved to be insensitive to penicillin. Insensitive organisms were finally found to persist in 11 cases, and these were therefore treated with tricresol; 10 of them were sterilized after an average of 5 weekly dressings. Of the remaining 9 cases only one was sterilized with penicillin; the remainder received dressings at regular intervals varying from 48 hours to one week without becoming sterile. One case received weekly dressings for 4 months, and on each visit a *Str. viridans* sensitive to penicillin was grown in pure culture. The case rendered sterile with penicillin had an acute periodontitis not related to a chronic inflammatory process of the periapical tissues and required 7 penicillin dressings at intervals of 48 hours before sterility was obtained.

Discussion

The problems met with in the treatment of infected non-vital teeth with associated chronic periapical osteitis are very similar to those presented by chronic bone infection in orthopaedic surgery. In both cases infected and, maybe, necrotic bone is present which is not easily accessible; and a further complication in pulp-canal therapy is the deliberate retention of these dead or relatively non-vital tissues. Robertson (1944) concluded that the local application of penicillin in cases of chronic bone infection has so far been disappointing, and cites three factors which appear to be responsible: (1) failure of continuous application; (2) inaccessibility of bone infection; (3) presence of dead bone.

Considering these points in relation to pulp-canal therapy, it is seen that:

(1) *Failure of continuous application* is equally applicable with the additional factor that as space is limited the amount of penicillin which can be applied must necessarily be small.

(2) *Inaccessibility* is certainly the case in dental pulp infections, since penicillin must diffuse through the apical foramina before the infected periapical tissues are reached.

(3) Whereas *necrotic bone* is not very commonly met in periapical osteitis following gangrene of the pulp, the cementum is often denuded of periodontal membrane, and when this occurs the source of its nutrition is cut off and the result is necrotic cementum. Cementum is histologically very similar to bone, and dead cementum is comparable to a sequestrum. Mowlem (1944) says that "penicillin is unlikely to give bacteriological control in the presence of sequestra," and the findings of this investigation confirm those of orthopaedic surgeons. One case out of 20 responded to treatment with penicillin alone, and radiographically no destruction of periodontal membrane was seen, so that it is just conceivable that no necrotic cementum was present.

The results of this investigation show clearly that penicillin administered as described is of little use in the treatment of infected non-vital teeth. Not only were half the cases ultimately infected with insensitive organisms but even those that were sensitive failed to respond to penicillin treatment.

We would emphasize that there has been insufficient condemnation of the practice of sealing into pulp canals organisms of unknown virulence and invasiveness. Adequate bacteriological control of pulp therapy is possible only through co-operation between the dental surgeon and the bacteriologist, and a satisfactory technique need entail no extra effort from the dental surgeon. Finally, any co-ordinated pathological service should be available easily and cheaply to dental surgeons as well as to medical practitioners.

Summary

A technique is described for the bacteriological control of dental pulp infections.

Of 20 cases examined 17 proved to be infected with *Str. viridans;* 14 of these strains were sensitive to penicillin.

In each dressing 50 units of penicillin were used, and dressings were done at 48-hour intervals.

Only one case was sterilized by penicillin, 7 dressings being necessary.

Eleven cases were infected with organisms which were insensitive to penicillin, and these were treated with tricresol, applied at weekly intervals. Sterility was obtained with an average of 5 dressings.

Eight cases continued to give cultures of an organism sensitive to penicillin even after prolonged treatment with this antiseptic, and these were finally treated with tricresol.

The similarity in the results of this investigation and those found in cases of chronic osteomyelitis treated with penicillin by orthopaedic surgeons is noted.

We are indebted to Mr. A. G. Allen, dental surgeon to the London Hospital, for helpful interest and for access to his patients; and to the Yarrow Fund for a grant to one of us (F. E. S.).

PENICILLIN IN WOUNDS OF THE CHEST

BY

A. L. D'ABREU, Ch.M., F.R.C.S.
Lieut.-Col., R.A.M.C.

AND

J. W. LITCHFIELD, B.M., M.R.C.P.
Major, R.A.M.C.

(From a British General Hospital, C.M.F.)

In the mass of literature dealing with penicillin therapy it is difficult to obtain a clear picture of what is practical and what is academic. We hope this short paper may be of value.

Since penicillin became available to this centre more than a year ago, over 500 penetrating wounds of the thorax have been treated. We believe that the therapy is best employed as follows.

General Parenteral Therapy

This is used only occasionally, and has not supplanted the well-established sulphonamide drugs, which may often be used with less distress to the patient, as they do not involve three-hourly injections. The indications are: (i) When pulmonary suppuration or severe infection exists with a pyothorax that is being surgically drained. Traumatic lung abscesses—i.e., around foreign bodies—infected missile tracks, and the rare breaking-down lung haematoma have been greatly benefited by general penicillin, which in these instances is more helpful than the sulphonamides. (ii) In severe chest-wall lesions, associated with an open sucking septic pneumothorax, which used to be a grave problem. Their closure after re-excision and removal of rib or scapula fragments (if necessary) is readily effected if combined with general penicillin, assisted in the first three days by local penicillin given by instillation tubes; no such case has failed to remain closed. (iii) For a simple or infected haemothorax general penicillin is of little or no value: it has been established (d'Abreu, Litchfield, and Scott Thomson, 1944) that local intrapleural penicillin is far more efficient as a bacteriostat for Gram-positive infection in such effusions.

Prophylactic Use of Local Penicillin, for Haemothorax

(*a*) *Primary Treatment (e.g., in Forward Units).*—Repeated intrapleural injection of penicillin without bacteriological and radiological check is unwise. The intrapleural injection of 60,000 units in 6 to 10 c.cm. (no more) at the end of the first two or three aspirations is advised; this injection in no way replaces adequate aspiration. As soon as the patient's general condition has been improved by these early aspirations he is usually fit for transfer to a general hospital or chest centre, where further treatment can be more satisfactorily carried out.

(*b*) *At General Hospital Level.*—At this centre the uninfected haemothorax is treated by aspiration without intrapleural instillations except under the following circumstances: (1) Where there is coexistent chest-wall sepsis. (2) When there is recognized or suspected pulmonary infection—e.g., when the radiograph shows a peripherally placed foreign body in the lung tissue or in the pleural cavity. Our practice is to remove such bodies as soon as the patient's general condition is satisfactory; if operation is delayed because of poor general condition and there is a coexistent haemothorax, this is treated by aspiration and intrapleural penicillin. (3) At the conclusion of a thoracotomy for foreign-body removal penicillin, 120,000 units in 10 c.cm. of saline, is instilled after air has been drawn off by an artificial pneumothorax apparatus. Unless there is infection of the pleural cavity, post-operative drainage is not done, and the resultant effusions are aspirated and bacteriologically examined as a routine. The missile bed is insufflated with penicillin powder before the lung sutures are tied.

Local Penicillin in Treatment of Infection

(*a*) *Intrapleural.*—Penicillin is of great value in the treatment of infected haemothorax and empyemata. It is obviously only of use in cases of infection by penicillin-sensitive organisms. Intrapleural therapy is useless for Gram-negative effusions and for penicillin-resistant staphylococci; it is therefore essential to have most careful bacteriological checks. All syringes used in this work require the most careful sterilization by boiling: no chemical method is safe enough prophylaxis: the more careful the technique the less frequent is Gram-negative infection. In an infected haemothorax or empyema containing penicillin-sensitive organisms our procedure is to aspirate the effusion and inject 120,000 units of sodium penicillin for large cavities and 60,000 units for smaller ones in 10 to 20 c.cm. of solution, on alternate days. The instillation is repeated until three specimens of the fluid have been reported to contain no pyogenic organisms on smear or culture. Frequent radiological location of the cavity is essential: even after the cavity is no longer seen radiologically its disappearance must not be assumed, and aspiration must be continued until fluid can no longer be obtained. Towards the end of this treatment the fluid becomes serous and the interval between aspirations can be lengthened to once or twice a week. Active breathing exercises are essential throughout the treatment.

Despite sterilization of the cavity, operative treatment is necessary in certain cases for the purpose of removal of clot and the prevention of excessive fibrin deposition on the pleura (parietal and visceral). The indications for surgery are as follows. (i) The presence of a sucking chest-wall wound in association with a pyothorax demands surgical drainage (closed) and penicillin closure of the wound. (ii) The presence of a large broncho-pleural fistula demands pleural drainage. (iii) The existence of a very large infected effusion associated with a total lung collapse to the mediastinum calls for closed drainage because in these cases so much fibrin is deposited that lung re-expansion and chest-wall movements are hampered; a few intrapleural instillations may be of great value before drainage, because the Gram-positive organisms may be eliminated, with a great decrease in toxicity. (iv) Considerable fibrin-clot formation, as shown radiologically or by repeated needle blockage during aspiration, is an indication for "clot clearance." If at operation a localized pocket is found and the organisms are penicillin-sensitive, complete chest-wall closure is followed by post-operative aspirations and local penicillin therapy. The larger cavities are drained for the reasons given above in (iii). (v) Persistent Gram-negative infection is a source of trouble because it leads to further exudation and fibrin deposition, thereby causing mechanical hindrance to lung re-expansion and chest-wall movements and continued toxaemia. Clot clearance and drainage are done for these cases after an adequate trial of repeated aspiration. We are using succinyl-sulphathiazole suspension for these aspirations, but this work is entirely in the experimental stage.

(*b*) *In Chest-wall Wounds.*—There is little to add to our previous published experience (d'Abreu, Litchfield, and Scott Thomson, 1944). Wounds that have been treated by excision and muscle closure of the pleural "suck" in the forward area arrive with the skin left deliberately unclosed: suture (delayed primary) is done soon after arrival with the assistance of penicillin–sulphathiazole powder. We excise septic chest-wall wounds, including the removal of rib and scapula fragments if necessary, and close them by suture with the aid of penicillin solution introduced by tube instillation: this is given for five days if there is underlying bony damage. The results are very successful even in the presence of frank pus. This method does not seem to be known widely enough. It is the solution of the problem of the septic open sucking wound (d'Abreu, Litchfield, and Scott Thomson, 1944).

We are indebted to Col. William C. McKinnon, the officer commanding, for permission to publish this paper.

REFERENCE

d'Abreu, A. L., Litchfield, J. W., and Thomson, Scott (1944). *Brit. J. Surg.*, **32**, 679.

C. F. Dixon and A. L. Lichtman (*Surgery*, 1945, **17**, 11) record their observations on 50 cases of congenital absence of the gall-bladder that have been recorded since 1900 and on 10 cases that have been observed at the Mayo Clinic. Symptoms resembling those of cholecystic disease were present in 58%; 48 had jaundice and 27 stones in the common bile duct. Symptoms were present in 73% of cases in which the patients were more than 45 years of age. Prolonged drainage of the common bile duct with a T-tube is advocated in the cases in which symptoms are present.

A CASE OF PENICILLIN REACTION

BY

W. MICHIE, F.R.C.S.Ed.
Major, R.A.M.C.; Surgical Specialist

AND

H. W. C. BAILIE, M.B., B.Ch.
Capt., R.A.M.C.; Resuscitation Officer

Unlike the sulphonamides, which soon after therapeutic birth began to show occasional reactions, penicillin has maintained a relatively unclouded reputation. Publication of the following case is therefore of interest.

Case History

On Sept. 7, while reconnoitring an enemy-held wood, a tank squadron commander was hit by a fragment of an 88-mm. shell which traversed his tank. The fragment—1½ by 1 cm.—which was embedded superficially in his lower lateral right calf, was removed an hour later and a sulphanilamide dressing applied. The officer remained on duty, but on Sept. 19 the leg became painful and the ankle swollen. He was admitted to a field dressing station, where sodium sulphate dressings were applied. On Sept. 24 sodium penicillin solution was instilled direct into the wound, with a similar application on the following day. On Oct. 2 he was admitted to a casualty clearing station, where a sinus 1 in. long was opened up. Since this officer was a key man urgently required by his unit, undiluted sodium penicillin powder (without sulphonamide vehicle) was applied in a much higher concentration than is normally employed, in the hope that recovery might be hastened. Similar application was made on Oct. 5. Progress was satisfactory, and on Oct. 10 the wound had almost completely epithelized. On Oct. 11 the patient intimated that he had a mild chronic bilateral external otitis. At 5 p.m. the same day two drops of sodium penicillin solution (100,000 units in 5 c.cm.) were instilled with a pipette into each ear. By 2 a.m. the next morning both ears were discharging profusely. His leg, previously almost healed, began to weep copiously, and literally saturated a moderately heavy cotton-wool dressing. The area affected corresponded roughly with that of previous dressings with which penicillin had made contact (Fig. 1). By evening, eczematous weeping patches had broken out over both ears, the lower face, and the chin. On Oct. 13 a penicillin patch test, consisting of two drops of penicillin solution on gauze, was applied to his arm. Within five hours the sensation was "similar to a T.A.B. reaction," and the next morning the patch area presented a weeping eczema similar to the areas originally affected (Fig. 2). A mild secondary infection of all areas subsequently developed. Healing ensued gradually after treatment with "nuflav" powder.

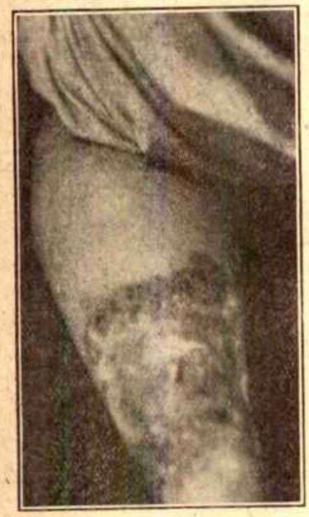

FIG. 1

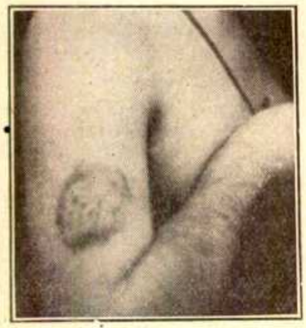

FIG. 2

The patient was seen again in December. The leg remained soundly healed but the chronic otitis persisted.

Comment

The particulars of the penicillin used at the field dressing station are unknown. That used in the ear and on the leg at the casualty clearing station was Pfizer batch 1664, and for the patch test Pfizer batch 1594. It is understood that the above is the only occurrence of a reaction of this type to penicillin therapy in more than 30,000 cases treated in the B.L.A.

No attempt is made to discuss the causative factors of the reaction, and it is impossible to tell whether it was due to penicillin itself or to associated impurities. Presumably, however, it was a matter of personal idiosyncrasy, since many other cases were treated with the same batches of penicillin and showed no reactions of any kind.

Our thanks are due to Lieut.-Col. R. Evans for permission to submit this report for publication.

SUBGLOTTIC STENOSIS AFTER EXPOSURE TO A HIGH CONCENTRATION OF SCREENING SMOKE (ZINC CHLORIDE)

BY

R. B. LUMSDEN, M.B., Ch.B., F.R.C.S.Ed.
Lieut.-Col., R.A.M.C.

AND

C. D. WEIR, M.C., M.B., Ch.B.
Capt., R.A.M.C.

On Oct. 3, 1943, in the Mediterranean theatre of war, Pioneer K., a Palestinian Arab aged 28, was exposed to an extremely dense cloud of screening smoke (zinc chloride) issuing from a room below, where smoke generators had exploded. He was one of seven casualties, three of whom died. The following is a record of his case.

Case History

On admission to a general hospital two hours after exposure the patient was found to be moderately distressed. He had a harsh cough with profuse frothy sputum, slight stridor, and vomiting. A few rhonchi were present. Oxygen was not required. Twelve hours later his temperature was 101.8°, pulse 135, and respirations 35. He complained of a sore throat and retrosternal pain and was coughing up frothy salmon-pink sputum, but was no longer distressed. Sulphapyridine was started. Blisters developed on the ears and hands. These were punctured two days later and straw-coloured fluid was evacuated (insufficient for chemical tests). Subsequent healing was uneventful and was not delayed. The bronchitis resolved in five days, leaving the patient apyrexial, with hoarseness and slight cough, and complaining of pain in the throat. The pharynx looked healthy. Indirect laryngoscopy two weeks after the accident revealed a yellowish-white membrane over the anterior surface of the larynx, involving both ventricular bands and vocal cords. There was some generalized oedema, and the entire larynx was of a dusky-red hue. Cord movements were normal. On Oct. 23 (three weeks after admission) he developed stridor, which passed off but recurred on a number of occasions, until on Nov. 2 tracheotomy (under local analgesia) became necessary. This was followed by a right basal pneumonia which resolved under sulphapyridine. By mid-November he was up and about, but on Nov. 18 laryngoscopy showed marked oedema of the arytenoids and ventricular folds, with stricture of the glottic aperture.

The patient came under our care in a Middle East General Hospital on Jan. 13, 1944, presenting the problem of reconstitution of an adequate airway. On admission his general condition was good. There were considerable congestion and oedema of both arytenoids and ventricular bands, redness of the vocal cords, and marked subglottic swelling. During the next six weeks he had two intercurrent attacks of bronchitis with pneumonitis, and one attack of tonsillitis which resolved rapidly under sulphathiazole but delayed any attempt to deal with the stenosis until March, 1944, when partial "corking" of the tracheotomy tube was tried out but could not be tolerated.

On May 17 (7½ months after the accident) direct laryngoscopy demonstrated marked subglottic narrowing, with granulations blocking the lumen. A portion of granulation was removed for examination, and the histological findings were: "Oedematous granulation tissue with fibrosis in the deeper layers. A tendency to haemorrhage is indicated by collections of haemosiderin-containing macrophages. The appearances suggest that it is some mechanical or chemical factor, and no infection, that is responsible for failure to epithelize." Blood Wassermann and Kahn tests were negative. During the next four weeks Jackson bougies (up to size 20) were passed on two occasions, and on July 26 continuous dilatation was instituted by means of a piece of stout rubber pressure-tubing about 2 in. long, the lower end of which was cut obliquely to enable it to lie immediately above the tracheotomy tube. This tubing was inserted into the subglottic position through the tracheotomy stoma by pulling on a stout silk thread passed down through a laryngoscope, brought out through the stoma, and stitched to the upper end of the rubber tubing. The other end of the thread was stitched to the lower end of the tubing, thus making externally a continuous circuit with the tubing in position. A second thread, stitched transversely to the lower oblique end of the rubber tubing, was anchored to the tracheotomy tube when in position. On two subsequent occasions, at fortnightly intervals, the tubing was replaced by a piece of larger bore, but on the latter occasion it would not pass through the tracheotomy stoma and was therefore introduced through the mouth, with the aid of the laryngoscope. A third attempt to replace this tube by one still larger was unsuccessful, and the same tube was reinserted with some difficulty, owing to persistent exuberant granulations. Some discomfort and swelling followed this manipulation, and continuous dilatation was stopped on Sept. 20. At that time it was feared that external operation would ultimately be necessary.

On Oct. 18 the airway appeared to be remarkably good, and direct laryngoscopy revealed the entire absence of granulations and a somewhat small healed lumen below the vocal cords. Dilatation from above by direct laryngoscopy and from below through the tracheotomy stoma was begun with Hegar's dilators—a procedure which the patient bore with remarkable ease. This was carried out on three occasions at weekly intervals, size No. 11 being easily passed on each occasion. During this period progressive "corking" of the tracheotomy tube was effected, and by Nov. 4 complete occlusion was being maintained throughout the 24 hours. Good movement of rather irregular vocal cords was observed on indirect laryngoscopy. The patient's voice was excellent, and he could undergo considerable exertion without embarrassment. On Nov. 18 —13½ months after the accident and 4 months after continuous dilatation was started—the tracheotomy tube was removed. The stoma closed in three days.

Having been discharged from the Service, he was allowed to return to his home, with instructions to attend the nearest hospital for subsequent periodic dilatation.

Comment

This case presents some interesting features: (1) In the literature which we have been able to consult we have failed to discover any reference to the occurrence of stenosis following exposure to screening smokes, and though reference has been made to the possibility of such an occurrence after exposure to mustard gas, no report of an actual case has been found. (2) The persistence of granulations, which disappeared only after continuous dilatation was abandoned—at which juncture it was thought that this method of treatment had been unsuccessful. (3) The employment of Hegar's dilators: the circumstances of this case justified any method of improvisation that was available. These dilators proved to be satisfactory and reasonably convenient.

Continuous Dilatation.—Brief reference to another case which came under the care of one of us (R. B. L.) illustrates the trial of a further method.

A lieutenant aged 25 was wounded in Syria in June, 1941. He was admitted to hospital with a large gaping wound of the right side of the face, mouth, and neck, with loss of a portion of the mandible and thyroid cartilage. A high tracheotomy and gastrostomy had already been performed. There was a fistula between the floor of the mouth and the neck wound, resulting in a constant flow of saliva to the laryngeal wound and tracheotomy opening. This was controlled by the frequent application of an improvised hand-suction apparatus by a special attendant. Six weeks after being wounded he was fit to have a low tracheotomy performed through a transverse incision. At the same time it was thought advisable to attempt to improvise a temporary method of continuous dilatation of the larynx in case this should subsequently prove necessary while the neck wound was still under treatment. A tracheotomy tube, to the end of which a piece of stout rubber tubing was attached, was inserted in an upward direction through the upper tracheotomy stoma. This was left in position for a day or two, in order to demonstrate that the method was satisfactory. Fortunately its later adoption was not necessary, as the larynx healed without any appreciable degree of stenosis.

Our thanks are due to Major-Gen. J. C. A. Dowse, C.B.E., *M.C.*, D.M.S., M.E.F., and to Col. G. H. Haines, *M.C.*, officer commanding a general hospital, for permission to publish this record. We are indebted to Major J. A. Kilpatrick, R.A.M.C., for the early notes on the case, and to Major W. S. Kerr, S.A.M.C., for his help in providing us with some of his personal instruments.

The Scientific Instrument Manufacturers' Association of Great Britain (123, Pall Mall, S.W.) announces that Mr. W. Bowen has presented a substantial capital sum, the income of which he wishes to be devoted towards the encouragement and development of invention, design, research, processes, and manufacturing technique in the scientific instrument manufacturing industry. The Council of the S.I.M.A. have drawn up a deed of trust under which the income from the fund is to be devoted each year to prizes to be awarded to the employees of members submitting papers fulfilling the objects of the Trust.

INTESTINAL OBSTRUCTION BY GALL-STONES

BY

MAURICE LEE, F.R.C.S.

Acute intestinal obstruction by gall-stones, although one of the rarer causes of bowel obstruction, has the highest mortality rate of all the obstructions of the intestine. Vick's (1936) figures are as follows:

Simple Obstruction	%	Strangulation	%
Intussusception	15·0	Strangulated inguinal hernia	20·0
Carcinoma	13·0	Strangulated femoral hernia	19·5
Adhesions	7·35	Strangulated umbilical hernia	5·4
Gall-stones	0·7	Other herniae	2·5
Congenital atresia	0·6	Internal strangulation	11·4
		Volvulus	2·6

Mortality of the Main Types of Acute Intestinal Obstruction

Gall-stone obstruction	50–60%
Carcinoma of colon	35–40%
Adhesions	30–35%
Internal strangulation	30–35%

The rarity of the condition is shown by the following figures. Barnard (1902), at the London Hospital in a period of 8 years, was able to collect only 8 cases of gall-stone obstruction—i.e., an average of one case a year. Gibson (1900), in a series of 646 cases of intestinal obstruction, had only 40 due to gall-stones. Prof. Grey Turner informed me that he has had 15 cases in all his surgical experience.

Many of the cases reported have been in very elderly patients, and in more than a few a second laparotomy has been required to remove a second stone. For example, Hinchey (1940) reported a case in a patient aged 79, and Dulin and Petersen (1939) had a patient of 83 who survived operation. Prof. Grey Turner (1932–3) reported a successful and very unusual case, in a patient aged 81, in which the obstruction occurred in the transverse colon. In my own case (described below) the patient was 87 years old and required two laparotomies within two months. The death rate (50%) is high because of two facts—late diagnosis (or no diagnosis) and the advanced age of the patient. Many of these cases give no history of previous gall-bladder trouble and have been quite well until the intestinal obstruction has occurred.

Gall-stones which give rise to intestinal obstruction are always large and have entered the bowel by a process of ulceration from the gall-bladder. The fistulous communication is usually between the gall-bladder and duodenum, though other internal communications have been described. Neligan (1915) reported an instance in which gall-stones were vomited into a pan by a patient with such force that the sound suggested a volley of buckshot being fired into a metal utensil. In this case the fistulous communication must have been between the stomach and the gall-bladder.

Not all gall-stones that get into the intestine cause acute obstruction. Some are passed naturally per rectum; others travel as far as the anus and there become impacted. It is very rare for the condition to be diagnosed previous to operation; a review of the literature reveals that only 7 cases were so diagnosed. In many cases the obstructive symptoms are at first temporary; the patient is relieved for a while and then the symptoms recur. This is very misleading to the diagnostician, and accounts for the high mortality of the condition. The remissions and recurrences of the obstruction are due to the fact that the gall-stone becomes temporarily obstructed in the bowel, is dislodged by vigorous peristalsis, and becomes impacted lower down in the bowel, where the lumen is narrower. It therefore follows that in most cases of gall-stone obstruction the stone is found obstructing the bowel in the terminal ileum. In my patient this occurred in the first obstruction, but in the second laparotomy the stone was found in the bowel much higher up in the ileum because it was a large stone and therefore could not travel further down. In view of the insidious onset of gall-stone obstruction and the difficulty in diagnosis of the condition in its early stages, the practitioner is faced with a case in which treatment is applied late, and perhaps when the patient is moribund. As in other types of intestinal obstruction, any means that can assist early diagnosis must be used. It is not even now generally realized that vomiting and abdominal pain which last for over 24 hours denote a serious abdominal condition. Again, too rarely is the stethoscope used to auscultate the abdomen. Just as a clinician can diagnose an abnormal heart sound or chest sound only by repeatedly listening to the normal sounds, so only by listening repeatedly to the normal sounds in a normal abdomen can he differentiate these from the abnormal conditions when they present themselves. The chief object of auscultation is to find out if borborygmi are absent or not. Increased borborygmi associated with pain suggest the presence of intestinal obstruction. Increased borborygmi without pain, on the other hand, signify bowel hyperactivity. A silent abdomen on auscultation indicates absence of peristalsis in the bowel and therefore the presence of ileus.

X-ray examination of the abdomen can be very helpful in the diagnosis of cases of intestinal obstruction running an obscure course. It must be emphasized, however, that the interpretation of straight *x*-ray films in the diagnosis of acute abdominal conditions must be made in conjunction with the clinical picture. In gall-stone obstruction the outline of a stone in the intestine may be seen (see Radiograph). This, of course, depends upon the amount of calcium salt present in the stone. But even in the absence of this or in other cases of intestinal obstruction a straight radiograph of the abdomen can often be of help in determining the degree of obstruction as well as its site.

Treatment

In gall-stone obstruction, operation at the earliest moment is the treatment of choice. Because of the excessive vomiting general anaesthesia should not be used. Once the stone is located the intestine over it is incised and the stone removed, the segment of intestine containing the stone having been isolated by careful packing. The incision in the intestine is then carefully sewn up, transversely if possible. The intestine should be examined for the presence of other calculi, but this examination should not be unduly protracted.

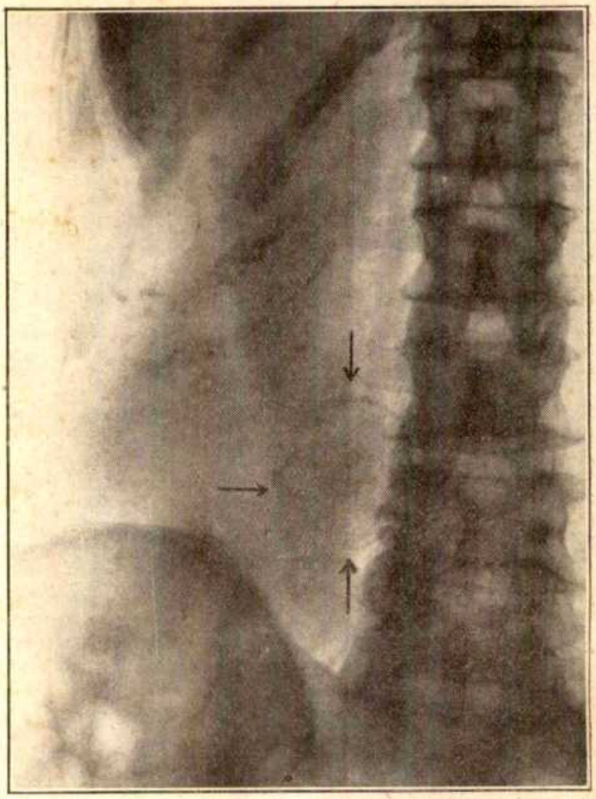
In the general textbooks on surgery it is advised that the stone be pushed into a segment of the bowel either proximal or distal to the site of the obstruction before the bowel wall is incised. In the two laparotomies which I have performed for this condition I found that this was impossible. The stone appeared to be grasped in the intestine in what seemed to me to be a state of spasm. It has been suggested that if this spastic condition could be overcome by injecting the mesentery of the intestine at the site of the obstruction by novocain 1%, the stone could then be milked along the rest of the ileum into the caecum, whence it would pass easily to the exterior. This procedure is feasible if the intestine is obstructed not far from the ileo-caecal junction and if the stone is not too large. In gall-stone intestinal obstruction there is not only an obstruction of the bowel lumen but also an additional spasm of the gut superimposed—a condition described in American textbooks as spastic ileus or dynamic obstruction. Certainly the less time that is taken and the less trauma there is in operations on these old and ill patients, the better is their chance of survival.

An alternative to this procedure is the possibility of crushing the stone *in situ* by the introduction of forceps into the lumen through a stab incision. Wangensteen (1942) states that he attempted this once, but was unable to crush the stone. In my own cases I noticed, while examining the stone (second stone at second operation) after laparotomy, that it crumbled up under the pressure of the scalpel when I attempted to divide it, much to my annoyance, as it would have made a lovely specimen.

Case History

The patient, a deaf woman aged 87, was admitted on Aug. 14, 1944, with intestinal obstruction. The obstruction had been absolute for three days and she had vomited everything for the same period. When she was admitted to hospital the vomit consisted of dark-brown foul material. There was generalized abdominal pain.

On examination, which was made difficult by her deafness, her tongue was dry and furred. The pulse was rapid and irregular because of auricular fibrillation. There was generalized tenderness and guarding of the abdomen but no rigidity. A glucose-saline intravenous drip was started and a laparotomy was performed under spinal analgesia, using heavy nupercaine. A large gall-stone about the size of a walnut was removed from the lower ileum; no other stones were found. After operation she had some diarrhoea and vomited for two days, but on Aug. 19—i.e., five days after operation—she was sitting up in a chair and taking a light diet.



Straight radiograph (portable) of abdomen showing large gall-stone in small intestine.

Second Operation, Nov. 26.—For two days previous to readmission there were vomiting, absolute constipation, and abdominal pain. At operation (under spinal analgesia) the old scar was excised. A large stone about the size of a golf ball was found obstructing the ileum about 3 to 4 ft. from the ileo-caecal junction. The stone was removed and the incision in the bowel wall was sewn up transversely. The post-operative convalescence was complicated by a discharge from the wound, which cleared up by the local application of sulphonamides. The stone was found on analysis to consist principally of cholesterol, with the addition of calcium carbonate and bile pigments. It was light in weight and crumbled into many pieces when an attempt was made to bisect it.

Summary

An explanation is given why gall-stone obstruction carries such a high mortality—namely, the insidious onset, the absence of any previous history, and the advanced age of so many patients.

A history is given of an elderly patient on whom two laparotomies were successfully performed.

Suggestions are made for dealing with the stone in order to avoid any further trauma to the bowel.

The Trustees of the Nuffield Foundation have agreed to give £30,000 for the provision of scholarships to enable promising officers of Dominion or Colonial origin in subordinate ranks of the Colonial Service to qualify for promotion, particularly in branches of the service where qualifications in medicine or biological subjects are required. Scholarships will be open to candidates of either sex and of any race. Awards will be made by the Trustees on the recommendation of the Colonial Office and the Colonial Government concerned.

Medical Memoranda

Ineffectiveness of Sulphapyridine and Successful Action of Sulphadiazine in a Case of Puerperal Fever

The following case is considered worth reporting, as one illustrating the comparative action of sulphapyridine and sulphadiazine in puerperal fever.

Mrs. P., a primipara aged 19, was delivered on Sept. 21, 1944, after a moderately prolonged labour; low forceps were used and episiotomy was performed under trilene anaesthesia. The infant weighed 10 lb. There was a slight rise of temperature to 99° during the first two days of the puerperium. On Sept. 26 the temperature suddenly rose to 104.6°, the patient developed rigors, suppression of lochia, and a pulse of 140, and felt very ill. Sulphapyridine orally was started at 6 p.m. the same day: 2 g. followed in 4 hours by 2 g., and afterwards 1 g. every 4 hours. The temperature on the 27th was 102.4° in the morning and 104° in the evening. On the 28th the morning temperature was 102.8°, evening 104°; two intramuscular injections of sulphapyridine were given at 1 p.m. and 7 p.m. on the same day in addition to the oral doses. Bacteriological examination of the blood showed that the causative organism was a haemolytic streptococcus. The morning temperature on Sept. 29 was 102.4° and the pulse 120. At 10 a.m. the sulphapyridine was stopped and 4 g. of sulphadiazine was given—2 g. at 2 p.m. and 2 g. at 6 p.m.—followed by 1½ g. every 4 hours until the evening of Sept. 30, and then 1 g. every 4 hours until Oct. 2. At 7 p.m. on Sept. 29 the temperature dropped to 101.6° and pulse to 120; lochia reappeared and the patient said that she felt much better. On Sept. 30 the morning temperature was 99°, pulse 110; evening temperature 98°, pulse 104. The respective temperatures on Oct. 1 were 97° and 98.4°; on Oct. 2, 96° and 96°; pulse normal. Sulphadiazine was stopped and the patient made an uneventful recovery.

COMMENT

Although the patient received large and regular doses of sulphapyridine orally and intramuscularly for 3 days, the infection showed no signs of regressing. Within less than 24 hours of starting sulphadiazine therapy there was a marked subjective and objective improvement in the patient's clinical condition with rapid resolution of the infection. The ineffectiveness of sulphapyridine in this case agrees with the experience of Dr. M. Kalisova in her recorded case of acute appendicitis (*British Medical Journal,* 1944, **2,** 597) in which penicillin was used after the failure of sulphapyridine to control the infection.

This seems to prove the superiority of sulphadiazine over sulphapyridine in combating streptococcal infections.

Nitrobenzene Poisoning from Furniture Cream

In view of the rarity of poisoning by nitrobenzene, we feel that the following case is of interest.

A man aged 45, who had been in the habit of taking an alkaline mixture, swallowed by mistake a quantity of furniture cream at about 8.30 one morning. He vomited about half an hour later; but as he felt ill he sent for a doctor, who saw him at 9.30 a.m. When seen he showed no sign of any untoward effect from his misjudgment. Later in the day he became drowsy, and when seen again by one of us (C. G. F.) at about 3 p.m. he presented a typical picture of methaemoglobinaemia, with marked cyanosis of the lips and conjunctivae.

He was admitted to hospital about half an hour later. His condition then was poor; he was semi-conscious, very cyanosed, and the pulse was thready. His stomach was washed out, a certain amount of the furniture cream being returned. He was then given 3 gr. of calomel. His condition steadily deteriorated, but we unfortunately were still unable to account for this. We then consulted our local chemist, Mr. T. N. Hitchings, who fortunately suggested the possibility of the presence of a benzene derivative in the furniture cream. On further reference, the identical symptoms were described as following poisoning by nitrobenzene. At about 10 p.m. he was given three pints of Group O blood, and about three pints was withdrawn. His condition gradually became better, full consciousness was regained, and his pulse improved. He made an uninterrupted recovery.

We have since learned from the makers of the furniture cream that the nitrobenzene content is from 4 to 5%. We conclude that the dose of nitrobenzene he had swallowed would have been about 15 minims, which we believe can be lethal.

We have since made contact with the makers and have suggested that, in view of the poisonous nature of the substance, it would be wise to market it in a distinctive bottle, suitably labelled.

Reviews

NUTRITIONAL KNOWLEDGE FOR RELIEF WORKERS

Nutrition and Relief Work. A Handbook for the Guidance of Relief Workers. (Pp. 111. 5s.) Published by the Council of British Societies for Relief Abroad in association with the Oxford University Press. 1945.

This book is intended to supply relief workers with the theoretical knowledge by which their activities should be guided and the practical instruction that will enable them to overcome the difficulties they will meet in the field. It begins with an account of the composition of food and the purposes for which the constituents of food are used in the body. This is very clear and written in non-technical language, and is followed by a discussion of the effects of undernutrition. It is welcome that this stresses the fact that partial starvation is not invariably accompanied by specific deficiency diseases; that the long extraction of flour and abundant consumption of vegetables, prevalent on the Continent, lessen the danger of such diseases.

Here will be found instruction on the conduct of surveys of the food consumption and of the nutritional state of populations, with examples of forms for use in such surveys. In order that relief workers may not offend against local tastes, customs, and prejudices, an account is given of food habits prevalent in various parts of Europe. A table shows the consumption per head of population, of various foodstuffs, in 16 countries before the war, in 1942–3, and in 1943–4. A chapter on classification and composition of food contains a table showing the calories, protein, fat, carbohydrate, calcium, iron, vitamins A, B_1, C, riboflavin, and nicotinic acid in the edible portions of foodstuffs, as purchased retail. There are also notes on the types of foodstuffs—for example, the composition of flour—now eaten in certain European countries.

Extremely valuable information is given about the handling and storage of foodstuffs. For example, there are full instructions about the storage of flour, whether white flour, high-extraction flour, or flour from mixed cereal grains; the ways of using dehydrated foodstuffs are described. The last chapter deals with various types of improvised equipment for cooking food. Finally there are appendices giving European currencies, weights, and measures, and an English–French–German glossary of words relating to food and cooking.

It is a remarkable achievement to have condensed so much information into a book of 111 pages. It is obvious that the authors possess first-hand knowledge of the matters with which they deal. Though the book is intended for intelligent amateurs, there are few among those who could be classed as professionals who would not find it valuable. The table of composition of foodstuffs, for example, contains information which is not collected in any other publication.

A TEXTBOOK OF MOSQUITO CONTROL

Mosquito Control. Practical Methods for Abatement of Disease Vectors and Pests. By William Brodbeck Herms, Sc.D., and Harold Farnsworth Gray. Second edition, revised and enlarged. (Pp. 419; illustrated. $3.50 or 20s.) New York: The Commonwealth Fund; London: Oxford University Press. 1944.

In the fight against malaria and yellow fever mosquito control is no longer a somewhat academic and experimental issue but is increasingly becoming a well-recognized special branch of public health work. An indication of the strides made in this direction and the highly developed techniques now employed will be apparent from study of the second edition of Herms and Gray's *Mosquito Control.* This very useful and attractive volume is without doubt the most complete account yet published dealing with the practical aspects of mosquito control as a public health measure. A notice of the first edition will be found in our issue of Jan. 18, 1941. The present edition follows in general the lines of the first, of which there have been three reprintings, but, as the authors note in their preface, the rapid development of new techniques of mosquito control in the past three years has made a thorough revision and enlargement of the book advisable to make it more applicable to the requirements of our military Forces and to the needs of occupational Forces later on. Apart from this very desirable end the new edition forms a valuable contribution to the literature on mosquito control under whatever conditions this may be carried out, as with the many additions in the text and additional or rewritten sections it brings the whole subject to a focus and up to date.

Of the fresh or revised sections the most notable are those dealing with the new larvicides, lethal sprays, and repellents, enlarged sections dealing with various forms of surface and subsoil drainage, and the expanded treatment of the now very important question of naturalistic methods of control. There is a new section on mosquito control under military environment, another on mosquito breeding in bombed areas. A chapter on the finding of mosquito breeding-places contains much fresh matter and useful instructions on methods of collecting larvae, while an appendix gives very clear and well-illustrated instructions regarding methods used in the identification of mosquitoes and the use of keys which should be very helpful to those without training in systematic entomology. What is also new is the large chart, for use in training centres, etc., illustrating species sanitation and giving the principal malaria-transmitting anopheles of the world grouped by regions and type of breeding-place, with the usually appropriate control measures to be adopted. The lists of selected works for consultation, at the end of each chapter, have been considerably added to, and there are some excellent new illustrations. Throughout the book is eminently practical, simply and clearly written, and up to date. Needless to say it should be in the possession of everyone concerned or interested in mosquito control work, whether in relation to antimalaria work, to control of *Aëdes aegypti*, or to abatement of mosquito nuisance.

NEUROPSYCHIATRY

Synopsis of Neuropsychiatry. By Lowell S. Selling, M.D., Ph.D. (Pp. 500. 25s.) London: Henry Kimpton. 1944.

This is a reference book for practitioners and students, setting out in the barest outline the essential facts of the various forms of nervous and mental diseases. The essentials of anatomy, physiology, psychology, and psychopathology are given—in the case of neurology with each chapter, and of psychiatry in three preliminary chapters. Neurology is dealt with on an anatomical basis, chapters being devoted to peripheral nerves, the spinal cord, the brain stem, the cranial nerves, the cerebellum, the cerebrum, the meninges, the autonomic system, muscle syndromes, and the convulsive states. Psychiatry is covered by chapters on basic principles, general aetiology, symptomatology, effects of brain trauma, neurosyphilis, alcoholism, drug addiction, the psychoses, the parapsychoses, the psychoneuroses, malingering, psychopathic personalities, behaviour disorders of children, and mental deficiency.

As may be seen, the book is comprehensive and on the whole fulfils its purpose, and may be recommended. It is easy to find faults and omissions in such a compilation—for example, there is no mention of cerebral malaria or trypanosomiasis, but the general practitioner (who unfortunately too often fights shy of textbooks of neurology and psychiatry) will find it very useful, and if it stimulates him to wider reading so much the better. The addition of notes on the military and medico-legal implications of the various conditions dealt with is of undoubted value, and if one might have wished for references to literature this is perhaps too much to ask for in a small volume. There is an adequate index which greatly facilitates reference. Proof-reading has not been too careful—e.g., "a small dose of luminal of half a gram."

HEALTH VISITING AND CHILD WELFARE

A Handbook for the Student Health Visitor. By Edith Wild, S.R.N., S.C.M., R.S.I. With foreword by F. T. H. Wood, M.D., B.S., D.P.H. (Pp. 66. 3s., paper boards.) London: H. K. Lewis and Co.

A Preliminary Course of Child Welfare. By D. A. Kennedy, S.R.N. (Pp. 80. 9d., plus 2d. postage.) London: The St. John Ambulance Association.

Health visitors are the field workers in public health, and they will find Miss Edith Wild's modest little book *A Handbook for the Student Health Visitor* a most useful guide. It is written with sympathy and humour out of an obviously wide experience, and its only fault—an unusual one—is its brevity. The chapters on how to look at babies and at toddlers are full of sound sense, and many medical practitioners will find the advice helpful. The notes on statistics and on co-operation with public officials are also of general application. It is possible that in years to come there may be a closer link between general practitioners and health visitors; if that becomes the case, then doctors will need a little book like this to explain the help they can secure. Meanwhile the health visitors themselves should make full use of it.

A Preliminary Course of Child Welfare, by Miss D. A. Kennedy, is published by the St. John Ambulance Association for its younger members. The material is well presented, with perhaps too much stress on clothing. More might have been said on milk as a food and on the need for boiling it: the scanty references to artificial feeding are commendable, but it is old-fashioned to talk of making cow's-milk mixtures resemble human milk, and unsatisfactory to refer students to the "directions on the tin" for dried-milk feeds.

CLINICAL PATHOLOGY

Clinical Laboratory Methods and Diagnosis. A Textbook on Laboratory Procedures, with their Interpretation. By R. B. H. Gradwohl, M.D., D.Sc. Volumes I and II. Third edition. (Pp. 2,130; illustrated. £5.) London: Henry Kimpton.

The immense compendium by Dr. R. B. H. Gradwohl of St. Louis, Missouri, U.S.A., entitled *Clinical Laboratory Methods and Diagnosis*, has appeared in its third edition in two large volumes. This work covers not only every aspect of clinical pathology but such subjects as museum technique, the bacteriological and chemical examination of foods, and crime detection by laboratory methods—indeed everything, and perhaps more than everything, that a pathologist may be expected to do. Its length is added to by its discursive style, by a profusion of excellent illustrations—some of which, though interesting, are superfluous (e.g., 6 photographs of cases of elephantiasis, and 4, including an almost full-page plate, of the marijuana plant)—and by such over-treatment of a subject as the 16 pages of tables of comparative results given by 30 different serological tests for syphilis. These are drawbacks only in their effect on price and weight, and the possessor will find these volumes an almost inexhaustible source of unfamiliar information, much of it contributed by experts in particular fields. New or revised subjects include the latest complexities of blood-grouping, the use of the photo-electric colorimeter, and the assay of vitamins and oestrogens.

Notes on Books

Lippincott's Quick Reference Book for Medicine and Surgery, by Dr. George E. Rehberger of John Hopkins University, first appeared in 1920 and now comes to us again in a twelfth edition (Philadelphia and London: J. B. Lippincott Company; 90s.). Those who are not acquainted with this tome will gather some idea of its scope and size from the subtitle—"A Clinical, Diagnostic, and Therapeutic Digest of General Medicine, Surgery, and the Specialties, compiled Systematically from Modern Literature"—and from the fact that the pages (10 in. by 7 in. and mostly printed in double columns), number 1,460, without reckoning the coloured plates. Its ten main parts (each with a thumb-index) cover almost the whole field of practical medicine except psychiatry. Each disease or disorder is treated alphabetically within the appropriate part, and there are five subsidiary parts, one listing all the drugs mentioned in the body of the work. In his brief preface Dr. Rehberger says that the sections on gynaecology and genito-urinary diseases have been entirely rewritten and all the other sections carefully revised in the light of the many new discoveries and developments which have entered the field of medicine since 1939. He mentions in particular chemotherapy, shock treatment, burns, deficiency diseases, and nutrition as having called for drastic revision of the text.

Dr. E. W. Caryl Thomas has prepared a new edition of his little *Synopsis of Forensic Medicine and Toxicology*, which made its first appearance in 1933. It is largely a reproduction of the previous issue, but there are signs of revision and amplification. As a means of rapid survey of the whole subject just before his examination the student will find it a useful supplement to his class textbook. The booklet is published by John Wright and Sons Ltd., of Bristol, at 10s.

The latest edition of the *Tuberculosis Reference Statistical Yearbook*, published by the New York Tuberculosis and Health Association, 386, Fourth Avenue, covers the year 1943, with comparative summaries for 1942 and for the five-year period 1939–43.

BRITISH MEDICAL JOURNAL
LONDON
SATURDAY APRIL 21 1945

MALNUTRITION IN SOUTH AFRICA

In 1938, in the four Provinces of the Union of South Africa, 58,165 European boys were examined by school medical officers and placed in one or other of the conventional groups of the Dunfermline scale[1]—(1) excellent, (2) good, (3) slightly subnormal, (4) bad—and 40.3% were placed in Groups 3 and 4 and therefore regarded as "malnourished." The term malnutrition has been extended, as in this country, to fit this classification. As here used it may include disturbances of metabolism, development, or function, due, for example, to disease or psychological maladjustment, beside those due to defects in the food. To find out how much of this "malnutrition" is caused by dietetic deficiency and to assess the value of methods used for detecting malnutrition, an intensive survey was made of 1,345 children, aged 8 to 16 years, in the Cape Peninsula. The results are discussed[2] by Prof. Brock, who directed the survey, and Dr. Latsky, nutrition officer of the Nutrition Section of the Department of Public Health. Children with evidence of active disease were excluded. The remainder were divided on the basis of the clinical examination into normally nourished (Groups 1 and 2 on the Dunfermline scale) and malnourished (Groups 3 and 4); but the results of other tests were given some consideration, especially when there was doubt about a child's group. The proportion of children classified as malnourished was 48.6% among Cape coloured children, 31.8% among children in schools in a native location, and from 17 to 65% in four European schools. The proportion was considerably higher in a school attended by poorer-class Europeans than among the coloured children. The relatively small proportion among the children of the native reserve, whose staple diet was mealie meal, was remarkable.

The results of seven other tests were considered in relation to this division. The mean haemoglobin concentration was 14.53 g. per 100 ml. in the normal and 13.77 g. in the malnourished groups. However, since haemoglobin varies with age and with sex above the age of 13, the significance of this difference cannot be appraised without a knowledge of the age and sex distribution in the two groups. Skiagrams were taken of the wrists of each child under standard conditions, and 420 (210 from each group of the same mean age) were compared. The average skeletal age of the normal group was 12.65 years; that of the malnourished group, 11.76 years. The method was, however, not very accurate; it was difficult to decide into which 6-month group an *x*-ray observation should be placed. No correlation was found between the urinary excretion of calcium, tested by the method of Sulkowitch, and the concentration of calcium and phosphatase in plasma; nor was plasma calcium below 9 mg. per 100 ml. or phosphatase over 12 Bodansky units higher in the malnourished than in the normal group. The average number of carious teeth per individual was remarkably small—0.7 in the malnourished and 0.5 in the normal group; the difference was not statistically significant. After a great deal of work it was decided that results obtained with the Birch-Hirschfeld biophotometer were so variable and subject to so much error that they could not be relied on as evidence of vitamin-A deficiency. No Bitot's spots or keratomalacia were detected; in a substantial number of children, especially among the coloured, dryness and roughness of the skin, particularly of the extensor surfaces of the upper arm—possible evidence of vitamin-A deficiency—were detected. The results of an ascorbic acid saturation test and the somatometric measurements were considered separately. The saturation test used was that of Wright *et al.*,[3] in which 14 mg. per kg. of body weight are injected intravenously and the urine is collected during the next five hours. Wright took the excretion of 40% of the dose in five hours as the lower level of normality. This test was done on 380 children. Baumann and Brock[4] consider that children who excrete between 36 and 39% of the dose cannot be regarded as suffering from vitamin-C deficiency to any important extent. Forty-three children excreted less than 40% of the dose, 24 between 36 and 39%, and 19 less than 36%. Latsky[5] discussed the A.C.H. and Tuxford indices in nutritional assessment. He concluded that by the aid of neither A.C.H. nor Tuxford indices was it possible to discriminate between malnourished and diseased children; a high proportion of children (12.5% by A.C.H. and 40.5% by Tuxford) who were normal according to the clinical examination were subnormal according to these tests. Of the whole number on whom the measurements were made 15.6% were subnormal according to the A.C.H. and 55.5% by the Tuxford index.

Another survey[6] was made of 7,000 Bantu children in three urban and six rural districts, using clinical examination and somatometric measurements, supplemented by estimations of haemoglobin and examination of urine and faeces for parasites. The proportion who showed evidence of disease and/or malnutrition in these nine districts ranged from 43 to 90%. The incidence of evidence of food deficiency among boys and girls was: well-defined phrynoderma, B. 12.7, G. 8.0%; pellagra-like dermatitis, B. and G. 1.8%; stomatitis (including angular stomatitis—most often dry, cracked, and frequently red, raw lips), B. 18.4, G. 9.6%; glossitis, B. 6.75, G. 3.8%; soft spongy gums, B. 3.2, G. 1.6%. The higher incidence of deficiency disease among boys may be due to the fact that the girls ate far more vegetables than the boys did.[7] (During the siege of Madrid glossitis was much commoner among females.[8]) Approximately 1 child in 5 had grossly carious teeth. The mean haemoglobin concentrations were: boys 12.2, girls 12.1 g. per 100 ml. A survey[9] was made among Europeans in rural areas with the object of discovering some of the causes of the widespread malnutrition in these areas. The farmers appear to depend too much upon bought foodstuffs and to consume too little of the dairy products and vegetables they might produce themselves. Socio-economic surveys in Cape Peninsula and in Witwatersrand show the familiar relation between malnutrition, poverty, and the number of children in a family, and the lower consumption of milk and fruit by malnourished children.

These investigations bring out the need to devise and standardize methods of assessing nutritional state. The proportion of children placed in Groups 3 and 4 even in the schools attended by the well-to-do was much higher than the proportion put in the corresponding groups in England and Wales; while it appears from surveys of food consumption that the diet of Europeans in South Africa does not compare unfavourably with British diets, and the death rates of infants and young children and the tuberculosis death rate are not those of a grossly undernourished people. However, standards differ widely. It is doubtful whether the results obtained by different observers, by methods which do not measure some feature in terms of precise units and give the results in figures, can ever be made comparable. Even methods that give results in figures are liable to error. It is fortunate that the Sicca method of estimating haemoglobin was used, since such Sicca apparatus as have been tested have proved to be accurately calibrated. But in comparing the results with those obtained in Britain by the Haldane method it must be remembered that 100% Sicca is 13.8 g. of haemoglobin per 100 ml., while 100% Haldane turns out to be 14.7 or 14.8 g.[10 11] It would be better if individual somatometric measurements were published, even if the author chooses to jumble them up in some index. The vitamin-C test employed is not a saturation test in the sense in which the expression is commonly used; it is unlikely that the results will be comparable with those of the tests in more general use.

The interest in nutrition roused by the results of the 1938 survey led to the establishment of a National Nutrition Council in the Union of South Africa,[9] under the aegis of the Department of Public Health. A great deal of research has been carried out into these methods of assessment. Such studies should not, however, be made in each country separately. It is essential that methods should be so standardized that the results will have the same meaning in any country. Valuable work along these lines has already been done by the League of Nations. Such standardization is needed now more than ever, since the privations of the war will stimulate nutrition surveys throughout the world. The Advisory Committee on Nutrition Surveys of the English Group of the Nutrition Society has, during the last six months, set up a standing committee, which includes scientists of 10 nations and has Prof. Fridericia as chairman, to consider and advise on this problem.

PATHOGENESIS OF CEREBRAL MALARIA

Infection of man with the malignant tertian malaria parasite, *P. falciparum*, is liable to result in a bewildering variety of clinical manifestations, of which one of the most important is cerebral malaria. The usual explanation of this grave complication is that the red cells parasitized by *P. falciparum* tend to adhere to one another and to the blood-vessel walls, and that thrombi composed of infected erythrocytes form in, obstruct, and distend small cerebral vessels. These red-cell plugs damage the contiguous endothelial lining, and blood from the damaged vessels causes the small haemorrhages to be seen post mortem, particularly in the white matter. Occlusion of the vessels cuts off the supply of blood to the areas involved and causes the mental and neurological changes indicative of the disease. This view of pathogenesis has been criticized as not wholly accounting for the development of the condition. Viswanathan[1] and Rigdon,[2] for example, put forward other hypotheses. The former reports 44 cases of cerebral malaria among 996 cases of malignant tertian infection. Of these 44, 8 patients died and were examined post mortem. Viswanathan asks why some only of a comparable series of healthy men suffering from subtertian malaria develop cerebral malaria, and why of these only some die, even while on prompt treatment, and others recover. In those who died, moreover, he found that death occurred even after treatment had been adequate to clear the peripheral blood and the cerebral capillaries of parasites. In histological studies of the fatal cases he found pigment but rarely parasites in the cerebral vessels. As a result of his investigation Viswanathan concludes that the primary lesion in cerebral malaria is damage by a malaria toxin to the capillary endothelial wall, and that thrombus formation occurs secondary to this, with accumulation of red cells and pigment, the presence of actual parasites in the plug being immaterial. In support of this thesis he cites five cases in which the cerebral attacks actually started in the absence of parasites from the peripheral blood, and in three of these which ended fatally no parasites were to be found in the cerebral capillaries.

From a wide survey of the literature on cerebral malaria in both man and experimental animals Rigdon arrives at different conclusions. He also is not satisfied that changes in the brain result from the formation of either parasitic emboli or thrombi, nor does he believe they are caused by the presence of malaria pigment in the capillaries. He points out that malaria toxin has never been produced *in vitro* or demonstrated *in vivo*, so he doubts whether a hypothetical toxin should be blamed for the cerebral lesions. Rigdon is more impressed by the degenerative processes seen in the brain cells, and by the absence of any excess of fibrin-like substances in the peripheral blood or in the cerebral capillaries of patients dying of cerebral malaria. He considers the degenerative changes in the walls of these small vessels to be the result of anoxia rather than of other pathological processes hitherto described. As a result of anoxia the permeability of the capillaries increases and blood leaks into the brain. Red cells also escape from the injured walls of the affected capillaries, so causing the appearance of capillary haemorrhage characteristic of cerebral malaria. Rigdon also blames the anoxia for focal degenerative changes in the myelin and in individual nerve cells throughout the brain. Comparable changes occur elsewhere in the body, particularly in the cardiovascular system, so progressively intensifying the cerebral anoxia until death results.

[2] *Southern med. J.*, 1944, 37, 687.

Neither of these alternative explanations of the cause of cerebral malaria can yet be accepted as being less open to criticism than the usual one. In the meanwhile it is generally agreed that the successful treatment of cerebral malaria depends on prompt and vigorous parenteral treatment of the parasitic infection with quinine or with mepacrine, and the intravenous administration of salt and fluid in the form of hypertonic glucose saline solutions.

DETECTION OF NICOTINIC ACID DEFICIENCY

Laboratory estimations of vitamin B_1, riboflavin, and vitamin C in body fluids, such as blood and urine, have proved a tolerably good guide to the level of these vitamins in the human subject. This is not the case with nicotinic acid, which is not excreted entirely unchanged but is partly converted into derivatives such as nicotinamide, coenzymes I and II (di- and tri-phosphopyridine nucleotides), and nicotinamide methochloride or a related substance. It was formerly supposed that nicotinic acid was excreted partly as trigonelline, but this is now disputed by Coulson, Ellinger, and Holden,[1] who believe that most of the so-called trigonelline is really nicotinamide methochloride. A few years ago attempts were made to diagnose nicotinic acid deficiency by estimating the urinary excretion of nicotinic acid or its derivatives, such as coenzymes I and II, in the blood. Experience has shown that such estimations are of little value for the laboratory diagnosis of disturbed nicotinic acid metabolism. Thus Spies and his co-workers[2] noted a wide variation in the nicotinic acid content of urine both in the same individual and from person to person; even in pellagrins the nicotinic acid excretion is stated not to differ significantly from normal.[3]

Najjar and his co-workers[4] claim to have devised a specific chemical reaction whereby nicotinic acid deficiency can be quantitatively measured. By the adsorption of urine on zeolite and treatment of the eluate with alkali and butanol they have obtained a fluorescent pigment called "F_2," which can be estimated fluorimetrically. The amount of F_2 excreted is stated to increase after the ingestion of nicotinic acid and several related compounds, and to be often absent from the urine of pellagrins. Further work by Huff and Pelzweig[5] suggested that F_2 was nicotinamide methochloride, but Ellinger and Coulson[6] showed later that nicotinamide methochloride is not fluorescent in aqueous solution. F_2 is probably derived from nicotinamide methochloride by the action of alkali, and according to Ellinger and Coulson is a mixture of the *o*- and *p*-carbinol of N-methyl-dihydronicotinamide. Najjar, White, and Scott[7] have recently isolated F_2 in crystalline form from urine and studied its properties. According to them it is derived from N-methyl nicotinamide-carbinol and is probably the butyl ether of this compound.

In his latest paper Najjar[8] proposes a test for the detection of nicotinic acid deficiency based on the measurement of N-methyl nicotinamide chloride in the urine instead of the fluorometric measurement of F_2. As N-methyl nicotinamide chloride can be conveniently prepared in the laboratory Najjar uses it as the standard of reference, the urinary output of N-methyl nicotinamide being expressed in terms of N-methyl nicotinamide chloride rather than in arbitrary fluorescent units of F_2, as done formerly. Najjar gives an oral test dose of 100 mg. of nicotinic acid, and estimates the urinary excretion of N-methyl nicotinamide during the following four hours. He considers an excretion of less than 2.1 grammes of the compound in this period to indicate nicotinic acid deficiency. Coulson, Ellinger, and Smart[9] have also used the assay of nicotinamide methochloride in urine as an index of nicotinic acid nutrition in R.A.F. personnel. The nicotinamide methochloride of Coulson, Ellinger, and Smart appears to be identical with the N-methyl nicotinamide of Najjar. This method needs further investigation before it can be accepted. Thus, Ellinger and Coulson[10] have shown that the excretion of N-methyl nicotinamide depends on a number of factors, including not only the intake of nicotinic acid and its derivatives but also exercise, food, the presence of methyl donators in the tissues, and the efficiency of the methylating mechanism of the body. Sargent, Robinson, and Johnson[11] consider that as a rule the level of F_2 in the urine runs parallel with the nicotinic acid intake, though they have observed well-nourished persons who excrete no F_2, and an excessively high excretion of F_2 during starvation. They also record that some subjects fail to show a larger excretion of F_2 after test doses of nicotinic acid. Mickelson[12] studied two groups of young men on daily intakes of 10 mg. and 20 mg. of nicotinic acid respectively for nearly six months, and failed to observe any significant difference in the F_2 excretion in the two groups. Furthermore there was no difference in the F_2 excretion in the two groups after a test dose of nicotinic acid.

It is clear that we still have no simple laboratory method for estimating the level of nicotinic acid nutrition in man.

CLEARING THE THROAT

Sulphonamide snuffs, first employed by Delafield, Straker, and Topley,[13] are of undoubted value in the treatment of nasal carrier states. The throat carrier presents a more difficult problem: the organisms are more deeply situated when the tonsil is involved, and the frequent swallowing of secretion prevents the long-continued action which can be secured by applying a powder to the nasal mucosa. All that we know about the sulphonamide effect on bacteria points to the necessity for continuous and prolonged action, and the throat is one of the most unpromising areas in the whole body for securing this. Nevertheless, attempts have been made to eradicate haemolytic streptococci from the throat, or at least to prevent their access to it, by the use of sulphonamide lozenges, and opinion on the efficacy of this proceeding has been divided. The sceptics will find strong support for their attitude in the observations reported by Vollum and Wilson in the opening paper of this issue. Opportunities for a controlled trial of the method were presented by outbreaks of haemolytic streptococcal infection involving a large proportion of the population of two schools. All the carriers having been identified, some of them were given lozenges containing sulphapyridine and sulphathiazole to suck, while the remainder were treated in other ways or not at all. The treatment was continued for from 5 to 7 days in two series with 6 and in one with 12 lozenges daily, containing 1/2 grain of each drug. Not only was there no effect on existing carriers, but 7 boys out of 24 so treated in order to prevent their acquiring the infection became carriers during the period of treatment. Although the total numbers concerned are not large, this study was so carefully controlled in every way that its conclusions must be accepted. Sulphonamide lozenge therapy, at least with these drugs in the doses used, is evidently useless. The dose given was presumably too small to produce a systemic effect, and a distinction should perhaps be drawn between this proceeding and the administration in ordinary tablet form of 1 gramme or more daily for prophylactic purposes. Much evidence has now accumulated that this serves to prevent relapses in rheumatic fever, and recent observations on a very large scale in American naval personnel support the conclusion that doses of this order afford some protection against acute infections. It is perhaps easier to curb the more violent activities of the haemolytic streptococcus than to prevent it altogether from establishing itself in the throat. A similar study to that now described by Vollum and Wilson, but conducted with penicillin pastilles as recommended by MacGregor and Long,[14] would be of great interest. Penicillin is a far more potent agent than sulphonamides; indeed, according to recent observations by the same authors,[15] it exerts an astonishingly rapid bactericidal action in the mouth. They obtained some evidence that penicillin pastille treatment will alleviate acute streptococcal throat infection and eliminate the organism itself, although in chronic tonsillar carriers it reappears after treatment has stopped. How far the use of these pastilles will succeed where sulphonamide lozenges have failed remains to be discovered.

POSTGRADUATE TRAINING FOR SERVICE M.O.s

In September, 1941, the Council of the B.M.A. decided to represent to the Government the need for suitable postgraduate training facilities for medical officers on their return from the Forces. Six months later the Goodenough Committee was appointed to consider, among other matters, arrangements on a national scale for postgraduate medical teaching and research. The committee recommended that the responsibility for postgraduate medical education should rest with the universities having a medical faculty, and that each of them should appoint a special committee for postgraduate medical studies, with a postgraduate dean to organize and supervise the arrangements. These recommendations were sent to the Minister of Health and the Secretary of State for Scotland in October, 1943, in advance of the committee's completed report, and it was then decided to set up at once the administrative machinery proposed by the committee. Since then the nature of the training facilities to be arranged by the universities for various classes of returning Service M.O.s, and the financial aid to be provided from public funds, have been discussed at conferences of university representatives held under the auspices of the Ministry of Health. The broad outlines of the Government's plan have now been published and are reproduced in the *Supplement* (p. 61). In some respects the scheme falls short of what the B.M.A. wanted. In particular a refresher course which may be taken in two weeks cannot be regarded as adequate for the "clinical rehabilitation" of the man recruited from general practice. There will be no dispute about the wisdom of providing opportunities for further hospital experience for the men who joined up within a year of qualification, but whether such men after four or five years' service will be attracted to resident posts carrying an annual salary of £350 is another question. If doctors in this group have acquired family responsibilities, however, salaries may be supplemented by a grant under the Further Education and Training Scheme arranged for ex-Service men and women by the Ministries of Labour and Education, and it is to be hoped that the help available from this source will be given generously. For the man aiming at a career as a consultant or specialist the salary proposed is more satisfactory, though here also some further help, which in this case would have to be provided for a period of years, might be necessary in individual cases. The promise of a post of the registrar type for the prospective specialist will allay the anxiety felt by many medical officers about their prospects of securing appointments of this kind on release. Throughout the discussions the B.M.A. representatives have emphasized the importance, in the public interest, of making the financial provision generous enough to attract the many Service doctors who will need professional re-education before beginning or resuming civilian practice. It is open to question whether this object has been wholly achieved. In other respects the arrangements for providing suitable hospital posts, including specially created posts where necessary, will be welcomed, and should materially help the younger Service doctors to make up for lost time in equipping themselves for the future.

FIJI LEPER SETTLEMENT

The Fiji Government has published a well-illustrated account of the Central Leper Hospital, Makogai, by the experienced medical superintendent, Dr. C. J. Austin. The island is a beautiful one, 2½ by 3 miles in extent, with separate villages for different races, for patients are admitted from the Solomon, Cook, and Gilbert as well as the Fiji Islands. There is a fine hospital with an *x*-ray plant and other buildings. Nursing is supplied by missionary sisters of the Society of Mary and native nurses trained by them to the great advantage of the settlement. Land is available for cultivation by the able-bodied; others are employed in fishing, building, etc., through which the patients earn money and the cost of living is reduced. Sports, concerts, and other amenities are provided, and religious services are conducted by resident or visiting clergy of several denominations. A Leper Trust Board, supported by New Zealand, runs a Christmas Day Fund and a comfort fund. The Fijian patients have increased from 352 in 1919 to 444 in 1943, but it is satisfactory to note that this is due to earlier admissions, for the number of early neural cases has increased from 0 to 27, and the advanced lepromatous ones have fallen from 32 to 0. Half of the hydnocarpus oil used in treatment is supplied by 1,000 trees planted in 1928. During the last ten years an average of 40 patients have been discharged yearly with only 10% of relapse, including those for trophic lesions in crippled nerve cases. The compulsory isolation system is believed to be a success.

Dr. H. Guy Dain, Chairman of Council of the B.M.A., has been elected a Fellow of the Royal College of Surgeons of England.

We are asked by the Central Medical War Committee to draw the attention of readers to an advertisement in our advertising columns this week for five general practitioners, one surgeon, and one pathologist for service with a large commercial company operating in the Middle East. The filling of these posts is an important and urgent matter, and the Central Medical War Committee will most carefully consider the possibility of any selected applicants within its jurisdiction being allowed to accept them.

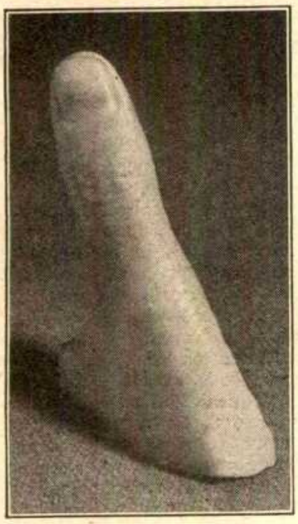
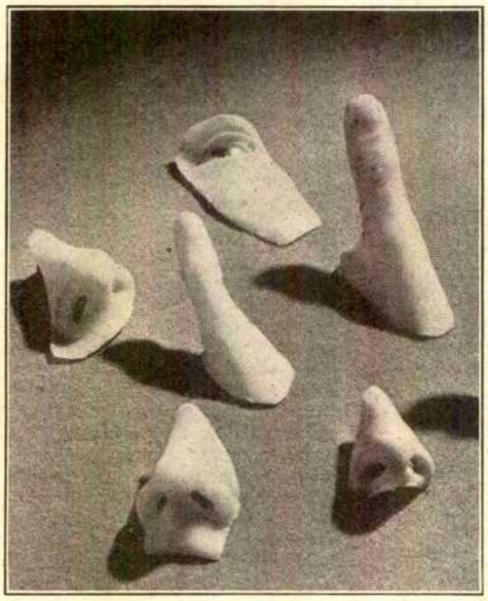
POLYVINYL CHLORIDE FOR PROSTHESES

[FROM A CORRESPONDENT]

Polyvinyl chloride (P.V.C.) compounds have had many and interesting applications during the war, notably for the sheathing and insulation of cables and for the proofing of fabrics. They are used also in the preparation of surgical prostheses, such, for example, as noses, ears, and fingers. War causes a large number of disfiguring injuries which severely tax both the skill of the plastic surgeon and the endurance of the patient. Treatment of such injuries generally involves a long series of operations and continual nursing care, during the course of which the patient's ability to co-operate may be impaired by the realization that he appears frighteningly disfigured. In addition to loss of tissue due to burns and injury, there is often a further loss by disease which it is generally impracticable to remedy by reconstructive surgery and which necessitates some form of false features or prosthesis.

Prostheses have been made for the plastic surgeon from metal painted to resemble tissue, gelatin-glycerin mixtures, vulcanite, wax, dental acrylic resins, and rubber latex. Of the hard materials, dental acrylic resins such as "kallodent," if prepared with skill, give the best result in cases for which a hard restoration is suitable, while rubber latex provides a good but much less permanent restoration. These prostheses may be attached to the face with adhesives or may be fitted to the frame of a pair of spectacles. Naturally, when the attachment is to the skin by an adhesive, the weight of the restoration must be small. Imperfections in fitting of the appliance and matching are generally corrected by cosmetic creams and powders, and the fatty basis of the cream may have a destructive effect on the fine edge of the rubber latex restoration. There is also a tendency for rubber prostheses to darken on ageing.





In view of the inertness and flexibility of plasticized polyvinyl chloride compositions, it was thought that they should be suitable for making prostheses. A considerable amount of work has therefore been done on the material by Imperial Chemical Industries, and is briefly recorded here with the aim of assisting those who wish to pursue the investigation.

It is well known that polyvinyl chloride swells in the presence of plasticizers such as tricresyl phosphate, dibutyl phthalate, or dihexyl phthalate, and may be dissolved at raised temperatures to form flexible rubber-like products. The physical properties of the resultant materials depend on the proportions and on the type of plasticizer used. The completely "gelled" plasticized compositions are thermoplastic and can be moulded by compression or injection methods. Polyvinyl chloride–plasticizer mixtures can also be prepared in the form of pastes, varying in consistency from thick cream to putty. These pastes can be transformed by heat to flexible rubber-like products and shaped during the process by a simple moulding operation. It was considered that this technique would be particularly suitable for making prostheses which are often complex in form and of varying thickness. It was realized, however, that care would have to be taken in choosing the most suitable ingredients for the composition for use in contact with the human skin. Tricresyl phosphate is very often employed as the plasticizer in polyvinyl chloride pastes, but for this application it was decided to use only phthalate esters as plasticizers—e.g., dibutyl phthalate and dihexyl phthalate. Again, lead salts are commonly used as heat stabilizers in polyvinyl chloride compositions, but were replaced by calcium stearate, a less toxic though less efficient heat stabilizer.

The following problems were investigated: (1) Development of a composition suitable for the production of an adequately flexible restoration, and having a reasonable shelf life. (2) Development of the best gelation technique—i.e., the optimum temperature that will give a restoration of the maximum strength. Thin edges may be needed for attaching the prostheses to the skin; they are not strong enough unless a relatively high temperature of gelation is employed. (3) Finding of a pleasing "base" colour. (4) Development of techniques to secure accurate fitting.

The use of dibutyl phthalate instead of the more usual tricresyl phosphate as the plasticizer introduced difficulties in obtaining a paste with an adequate shelf life, and it was finally decided that, for the time being, the paste should be made from the polymer and the plasticizer immediately before use. Polyvinyl chloride compositions are more flexible when plasticized with dibutyl phthalate than with an equal amount of tricresyl phosphate.

A temperature of gelation of 140° C. gave satisfactory restorations, but difficulties arose from discoloration of the composition, particularly because of the omission of a lead salt stabilizer. A wide range of satisfactory pigments has not yet been developed, but good results were obtained in a "natural" pink shade by the use of cadmium red with a white pigment. Titanium dioxide was used at first for this white pigment, but zinc oxide gave better colour stability.

The method of making a restoration—e.g., a nose—is as follows:

The nose is made in wax or "plasticine," modelled either to the patient's face or to a plaster mask of the face secured by a moulage method. The wax or "plasticine" is then invested in one half of a large dental flask in plaster-of-Paris. When the plaster has set the "plasticine" is removed and new hot wax poured into the cavity to replace it to a uniform thickness all round the mould, thickening where this is necessary—for example, at the tip of the nose—but realizing that the thicker the wax the heavier the final restoration will be. Plaster-of-Paris is then poured in and the reverse half of the flask filled with plaster and closed. When this investment has set entirely, the flask is placed in boiling water until all the wax is removed. The flask and plaster investment are then thoroughly dried out in an oven to ensure that the necessary temperature of gelation will be attained. When quite dry the mould is removed from the oven and allowed to cool to a temperature of about 50° C.

Pigmented polyvinyl chloride powder is stirred with dibutyl phthalate in a mortar until a smooth paste is obtained. Equal parts by weight of the plasticizer and polyvinyl chloride are convenient proportions, but the result may be made more flexible or less flexible as desired by increasing or reducing the amount of plasticizer. Ability to form pastes depends on the type of polyvinyl chloride, and specially prepared "corvic" polymer was used in these experiments. The mould is then filled with the polyvinyl chloride paste, possibly tinted in addition to match more closely the skin adjacent to the particular restoration. The flask is secured, replaced in the oven, and left for one hour at 140° C. After gelation the flask is taken from the oven and allowed to cool, when the restoration is removed and trimmed. The prosthesis may be fixed by means of adhesives such as gum tragacanth or spirit gum, or by conventional methods involving attachment to spectacles. Metal moulds give a better surface to the prosthesis, but such moulds are less easy to prepare than those of plaster. Additional paints to help in matching the prosthesis to adjacent tissue have been developed by I.C.I.

The illustrations show some examples of the type of work made with polyvinyl chloride pastes, and the simplicity of these methods suggests many applications.

GUESTS FROM LIBERATED EUROPE

Many professional and other people in the liberated countries are keenly anxious to renew contact with their colleagues in Britain, and arrangements were made for visits by representatives of French doctors, the Belgian universities, and French school-children. A French medical delegation of 10 has been here from April 7 to 17 as guests of the British Council, in conjunction with the Royal College of Physicians, and were entertained at functions by other organizations, including the Royal Society of Medicine. The delegation saw hospitals in London and elsewhere, and visited Oxford and Cambridge. The members were:—Académie de Médecine: Prof. Baudouin, Dean of the Faculty of Medicine, Paris, Prof. A. Lemierre, and Dr. P. F. Armand-Delille; Conseil Supérieur de Médecine: Dr. Ravina, Dr. A. Laporte, and Dr. H. Descomps; Provinces: Prof. C. Soula (Toulouse), Prof. Gernez-Rieux (Lille), Prof. Roche (Marseilles), and Dr. Nedelec (Angers).

The first of four groups of Belgian professors representative of all Belgian universities are here from April 16 to 30. The other groups will follow at intervals between May and July. The members of the first group are: Prof. V. Bohet, Professor of English, Liége; Prof. N. Goormachtigh, Faculty of Medicine, Ghent; Prof. P. Govaerts, Faculty of Medicine, Brussels; Prof. M. F. L. Hemptinne and Prof. C. J. Jungers, Faculty of Science, Louvain.

The French school-children, six boys and six girls, came at the invitation of the Lord Mayor of Birmingham and the city's schools and with the assistance of the British Council.

Prof. L. P. Garrod lectured in Paris under the auspices of the British Council, and published an account of his impressions in last week's *Journal*.

BRITISH COUNCIL FOR REHABILITATION

The establishment of a British Council for Rehabilitation, under the chairmanship of Lord Rushcliffe, is a further indication of the place now rightly accorded in our national life and thought to the problem of the health and resettlement of injured and disabled persons, one which was recognized by the Government last year when it passed the Disabled Persons (Employment) Act. Among the objects of the council are: (*a*) To act as a central co-ordinating body for the various interests concerned in the widest aspects of rehabilitation. (*b*) To promote and correlate courses of study. (*c*) To invite the active co-operation of Government Departments, hospitals, universities, training colleges, educational institutions, and research foundations in promoting the study and practice of rehabilitation. (*d*) To secure the active co-operation and participation of commerce, industry, and professional bodies in the problems of resettlement. (*e*) To encourage the formation of follow-up schemes for the rehabilitated. (*f*) To consider, promote, or oppose legislation which may affect the interests of the disabled and to make such representations as may be desirable.

The council will comprise two representatives from each of the member organizations, a number of elected members, with such others as the council may from time to time appoint provided the total of elected members does not exceed half the number of representatives; and two delegate members from each regional council that may be set up.

The member organizations are: Association of Industrial Medical Officers (Drs. N. T. Glynn and C. L. Potts), Association of Occupational Therapists, Board of Registration of Medical Auxiliaries, British Federation of Social Workers, British Hospitals Association, British Legion, British Medical Association (Mr. A. M. A. Moore and Dr. J. A. L. Vaughan Jones), British Orthopaedic Association (Mr. W. Gissane and Air Commodore H. O. Clarke), Central Bureau for Insurance Nursing Ltd., Central Council for the Care of Cripples, Charity Organization Society, Chartered Society of Physiotherapy, Hospital Almoners' Association, Industrial Orthopaedic Society (Sir Ambrose Woodall and Mr. Percy F. Pollard), Industrial Welfare Society, Institute of Labour Management, Miners' Welfare Commission (Mr. E. A. Nicoll), National Association for the Prevention of Tuberculosis, National Council of Social Service, National Institute for the Blind, National Institute for the Deaf, National Institute of Industrial Psychology (Dr. S. L. Simpson), Research Board for Correlation of Medical Science and Physical Education, Roffey Park Rehabilitation Centre (Dr. Ling), Royal College of Nursing, Royal Faculty of Physicians and Surgeons of Glasgow (Dr. G. H. H. Stevenson), St. Dunstan's, Scottish Orthopaedic Council (Mr. Alexander Miller), Society of Medical Officers of Health (Dr. James Ferguson), Spero Fund for the Industrial Welfare of Tuberculous Persons, Trade Union Congress.

The elected members include Dame Georgina Buller, Mr. N. St. J. Buxton, Mr. Norman Capener, Dr. F. S. Cooksey, Mr. E. S. Evans, Mr. H. E. Griffiths, Mr. S. L. Higgs, Dr. H. Joules, Dr. R. L. Kelham, Prof. J. M. Mackintosh, Mr. S. A. S. Malkin, Mr. Donald C. Norris, Dr. J. D. Robertson, and Mr. R. W. Watson-Jones.

Funds are needed if the council is to be a success and to do all that has to be done for the injured themselves and for their resettlement in productive activities. Donations should be sent to Mr. H. Vezey Strong, at the council's offices, 32 Shaftesbury Avenue, London, W.1.

Reports of Societies

PENICILLIN TREATMENT

At a meeting of the Manchester Medical Society on March 7 Dr. G. S. SMITH opened a discussion on penicillin.

In his introduction he emphasized that the choice of cases and the control of penicillin treatment had to be based largely on bacteriology. He outlined the principles involved and described the methods of giving penicillin and its dosage in systemic and local use. He mentioned that although the continuous intramuscular drip for systemic treatment had its own difficulties it was generally preferred to the interrupted three-hourly dosage in seriously ill patients. A review of the first 100 cases receiving penicillin treatment in the Manchester Municipal Hospitals was summarized as follows:

(1) In 13 cases of osteomyelitis there were good results, but penicillin did not prevent the development of a local abscess in bone or periosteum, which always required surgical treatment. (2) Of 10 patients with septicaemia (eight staphylococcal, one *Streptococcus pyogenes*, and one a non-haemolytic streptococcus) seven recovered after seven days of full systemic treatment and one died from pericarditis. (3) In 15 adults with pneumonia who had failed to respond to sulphonamides or were unsuitable for sulphonamide treatment the general symptoms improved in all cases but two, where the temperature did not fall satisfactorily and they had deep empyemata. Five patients in this group died, four from bacterial endocarditis and one from acute nephritis which was present before the pneumonia started. Seventeen infants and young children, mostly after whooping-cough, had bronchopneumonia; here the bacteriology was uncertain, but penicillin was tried after the failure of sulphonamides and 12 did well, while five died (two within four hours of starting treatment). Prolonged treatment was necessary in these cases, the response being rather slow, and a second course was sometimes needed. (4) Six cases with empyemata, four in children and two in adults, were given penicillin locally to sterilize the pus in the chest, followed by drainage in each case, the results being satisfactory. (5) Nine cases of uterine sepsis, after pregnancy or abortion, that failed to respond to sulphonamides were due to *Streptococcus pyogenes* (five), *Staphylococcus pyogenes* (two), and *Cl. welchii* (two); recovery followed in all but one patient who died before penicillin could have had any effect. (6) Three women and one man with a long history of unsuccessful sulphonamide treatment for gonorrhoea responded well to penicillin. (7) Three patients with cavernous sinus thrombosis, all staphylococcal in origin, recovered after intensive penicillin therapy, though one patient died some months later from staphylococcal arthritis of the hip-joint. (8) Four patients with meningitis had intrathecal penicillin; from one of these a penicillin-sensitive *H. influenzae* was isolated, and this child had lumbar puncture and intrathecal penicillin twice daily for six days. All four recovered. (9) In 20 patients with severe local sepsis, mostly staphylococcal in type, the results were generally good; one patient with a severe anthrax lesion on the face responded well.

Prof. J. MORLEY, after quoting the good results that were being obtained in the Italian campaign, thought that in civilian cases penicillin would be more suitably given by continuous intramuscular drip, thus requiring a trained nurse all the time, and in consequence it could not be satisfactory as a domiciliary treatment. Dr. B. WOLMAN quoted cases treated with penicillin, and Dr. P. GABARRO referred to its value in plastic surgery. Dr. H. J. VOSS mentioned the use of penicillin cream on carbuncles, and said that it was necessary to continue penicillin treatment for a very long time in cases of puerperal fever, white-leg, etc. Mr. F. ROBINSON said it should not be forgotten that the good results obtained in plastic surgery were only in part due to the use of penicillin; they were primarily due to the very careful technique carried out by plastic surgeons who paid close attention to the principles of surgery in dealing with the injuries: removal of dead tissue and dirt, early closure and early skin grafts leading to complete healing by first intention.

Nova et Vetera

SIMON LUDFORD, M.D.

Munk in the *Roll of the Royal College of Physicians* (vol. 1, p. 64) has a good deal to say about Simon Ludford. Apparently he was originally a Franciscan friar and later a London apothecary. The University of Oxford admitted him M.B. in 1554. Not content with this the University, in the following year, admitted a coppersmith, David Laughton by name, also M.B. The College of Physicians looked upon each as "ignorant, unlettered, and incompetent," and reproved the University by letter for its laxity and advised more cautious conduct in the future dispensation of medical degrees. The University seems to have revoked its licences to practise, and the coppersmith appears to have reverted to his original occupation. Ludford was more persevering. In 1560 he was admitted M.D. at Oxford, and in 1563 F.R.C.P. He even rose to the dignity of a Censorship on three occasions. He died in October, 1575. I give an abstract of his will:

> Symon Ludford, Doctour in Phisick, dated 1, July 1575. (P. C. C. Pickering, 38.) Sowle into the handes of all mightie God the father my creator, the Sonne my redeemer and the holie Ghost my comforter . . . in whome onlie . . . I hope to have the fruycon [fruition] of the presence of the deitie with the electe. My bodie in St. Steven in Walbroke where I am now a parishyoner: suche debtes and dueties as I doe owe shalbe trewlie answered and paid. All suche my goodes, chattalls, householde stuffe shalbe parted into three equall and indifferent partes accordinge to the use and custome of the Citie of London, whereof one parte I give to Jane, my loveing wief, the seconde parte unto William Ludforde my sonne, the thirde parte I reserve to myself. I wille that there shalbe made and preached at my buriall to the edeficing of Gods churche one sermon by Mr. Nowell,* Deane of Pawles (if he may be hadd) and I give to him for his pains 20s. To my Companie of Grocers in London that shall goe with my bodie to the murialle £6.13.4 for a recreation amongest them to be hadd. To Jane Martin, the child that now dwelleth with me, £20 when 18. The lease of my great messuage and the houses belonging to the same not to be praised [appraised, or valued] with the rest but my wif to have the use and custodie and there dwell with the use of all the wainscott sethinge and seling† fastened to the same. 40s. to the hospitals of St. Thomas in Southwarke, St. Bartholomew in Smithfeld and to the late erected hospitall called Christs Hospitall. £3 among the poor prisoners of the six prisons, Newgate, Ludgate, the two compters, the Marshallsee and Kings Bench in Southwarke. Servant, James Armeson £4. Maid, Jane Franklin £4. Residue, wife Jane. Friends Edward Skeggs, Poulterer, Robert Frier, citizen and goldsmith, overseers. Signed and sealed 14, october. Proved, 27, october 1575. (4 witnesses.)

I like to think that Ludford surmounted the difficulties of his early medical career and died in the odour of professional sanctity as M.D. The will shows that he was still a member of the Grocers' Company at the time of his death, for he left money for the customary funeral feast. At this date the Society of Apothecaries had not been founded, and those who practised this craft were members of the Grocers' Company. I can't help wondering whether the College of Physicians altogether approved of one of its Fellows being an apothecary member of the Grocers', but there is nothing in Munk to show that it objected.

The tripartite division of the goods of the deceased according to the custom of the City of London is extremely ancient, and goes back to Anglo-Saxon times in England. I owe the transcript of the will to my friend the late Mr. Harvey Bloom.

R. R. J.

The *Scotsman* recorded lately the severance of one of the remaining links with Lord Lister. Mr. Andrew Brown, who has died in his 94th year, was engaged in business as a maker of hospital appliances in Glasgow until he retired in 1939. He made sterilizing apparatus for Lister during his service at Glasgow Royal Infirmary and was personally acquainted with him. Not long ago he presented to the Glasgow Corporation a steam carbolic spray made to Lister's instructions in the earliest days of antiseptic surgery. Andrew Brown became a Burgess of his native city.

Correspondence

Women in Labour

SIR,—I can well believe that nothing other than humanitarian motives has led Dr. John Elam to write the letter on women in labour. Furthermore, I can well imagine that many of the facts contained in his letter are in the main accurate, and it seems certain that in our maternity hospitals full use is not being made of the methods of analgesia now available. That this failure to afford relief to the sufferings of women in labour is due to any "indifference" or callousness on the part of the obstetricians I hasten emphatically to deny.

Surely Dr. Elam must be aware of the difficulties under which institutional midwifery is being conducted at the present time—difficulties which show little sign of any abatement in the near future and which are daily and nightly causes of grave anxiety to those of us who are resident obstetric officers. Owing to the changed social conditions more and more women are compelled to seek admission to hospital for confinement, the population of all industrial areas has steadily increased, and the average age of primigravidae has shown a distinct upward tendency in the last few years. These factors have all tended to increase the work of our maternity hospitals, and the demand for maternity beds is now greater, more pressing, and more insistent than at any time since the outbreak of war.

To add to the difficulties the shortage of nursing staff is notorious and continues to be a "national problem"; this factor alone has of necessity led to a lowering of the standards of institutional midwifery until it is clear that the margin of safety has disappeared, and those of us engaged in the practice of this branch of obstetrics know full well that a sharp rise in maternal mortality is now inevitable.

These matters may or may not be capable of a speedy solution, but if solution there be, it must clearly be on a national basis, and no local effort is likely to achieve success. We working obstetric surgeons are certainly powerless to alter them. For some years our utmost endeavour has been to keep the maternal mortality figures as low as possible and to preserve the lives and health of the women and infants given into our charge. In this critical phase of the country's maternity services, it does seem that to castigate us for failure to relieve pain by the use of gas-and-air analgesia is, to say the least, untimely.

Regarding the technical aspect of the question, I would point out the difficulties encountered either in purchasing new anaesthetic apparatus or in having faulty instruments repaired. Furthermore, as Dr. Elam is well aware, the gas cylinders of various types of machines are of different sizes and therefore not interchangeable. Trilene-and-air anaesthesia is still very much on trial, and recent papers dealing with trilene anaesthesia clearly show that trilene is a substance which possesses many grave disadvantages as an anaesthetic agent. It cannot in the existing state of the law and the rules of the Central Midwives Board be administered by midwives, and an obstetric officer who permitted it to be administered by anyone other than a registered medical practitioner could not hope to escape the legal consequences of an anaesthetic death.

In conclusion may I refer Dr. Elam to a recently published report on "A National Maternity Service," pages 30 and 31, in which it is clearly indicated that the widespread use of analgesia in labour can only be hoped for when in this country we establish in the future a maternity service of the type recommended by the Royal College of Obstetricians and Gynaecologists.—I am, etc.,

WILLIAM J. CLANCY,
Obstetric Officer.

City General Hospital, Sheffield.

SIR,—As one who has had two children in the past two years I should like whole-heartedly to endorse the sentiments expressed in Dr. John Elam's letter. In furtherance of the object of analgesia in childbirth, I suggest that the following be incorporated in the routine of antenatal care:

(1) Instruction in the art of relaxation. I do not think that, as is so often claimed, this mitigates the severity of the individual

---

* Alexander Nowell, Dean of St. Paul's. See *Dictionary of National Biography.*

† Sethinge and seling. I cannot explain the meaning of this, but suggest that it may mean tapestry which covered the walls and ceiling. I have never met the words in any other ancient will, but wainscot is referred to occasionally.

pains, but I am convinced that it hastens the dilatation of the cervix. (2) Instruction in the use of gas–air apparatus, stressing the following points: (*a*) The mask to be held close to the face, and the patient to breathe deeply during the pains. (*b*) When the pains are coming frequently and severely (at a point, of course, to be judged by the attendant doctor or midwife) the patient to breathe *normally* into the mask between pains. Thus a certain concentration of nitrous oxide is maintained in the lungs and the maximum is easily reached by deep breathing when each pain starts. (3) Reassurance; tell your patient she won't be allowed to suffer: thus fear, the great inhibitor of uterine action, is removed. In order to carry this out every practitioner should familiarize himself with one method of drug analgesia in obstetrics, such as omnopon, scopolamine, seconal, etc.—I am, etc.,

Woman Doctor.

Trichlorethylene in Midwifery

Sir,—I have read Dr. D. C. Devitt's letter about trichlorethylene (March 24, p. 422) with interest and agreement. After using Marrett's inhaler (with the addition of a handle cum rack for mask) for two years I, too, find it superior to gas–air in labour. One advantage is that if the nurse takes over from the mother and uses full-strength vapour straining is stopped and the head can be extracted with complete concentration on the job.

A field in which, I think, trilene could be extended with advantage in general practice is as an adjuvant to nitrous oxide in dentistry and for young children. I suppose one may sufficiently anaesthetize 98 to 99% of individuals with gas for dental extractions, but, in my hands at any rate, quite a large proportion complain of nausea or vomiting afterwards and are unfit to go home without a considerable rest. By using a small bottle with a wick as supplied with some gas machines and a few drachms of trilene, cyanosis can usually be avoided and a much less upsetting administration secured without the unpleasant attentions of the dentist who may force an ether-soaked swab into the mouth. Children take trilene with gas particularly well. I may instance my own boy, who, after a 20-minute administration for discovery and removal of a needle from the thigh, went into a normal sleep without retching and woke without knowing that anything at all unusual had happened.—I am, etc.,

Birmingham. W. Brian Gough, M.B., D.A.

Unilateral Hypotony during Anaesthesia

Sir,—The article by Drs. Ina and G. J. C. Brittain on unilateral hypotony during anaesthesia (March 31, p. 442) should, I think, be regarded as a warning of what can be done unthinkingly in the cause of healing. It is to me almost unbelievable that anyone should have so little imagination (quite apart from the lack of good technique involved) as to inflict on a patient what is therein related.

"That first fine careless rapture," sometimes to be observed in those feeling the freedom of a recently acquired facility in any specialty, may be noticed even among anaesthetists, and it is sometimes detectable in the manner in which a mask is clamped upon a patient's face and thus left. Harness, by reason of the mechanical thrust involved, tends to impair the airway, and because of its labour-saving properties tempts the unwary to do no more than apply it; the result can be an airway far from perfect, and, apparently, trauma such as has just been reported.

It would therefore seem reasonable to hope that the young anaesthetist will at first eschew the lures of harness and whenever possible learn to procure a good airway by manual manipulation, and, having acquired this facility, continue to use harness only when absolutely necessary (for example, closed circuit); and further that the mask will be chosen and applied and the harness adjusted with care and discretion, with no hesitation to use the hands afterwards as occasion demands.

Mechanization has its uses, but unthinkingly applied is not necessarily progress.—I am, etc.,

London, N.W.11. Stephen Coffin.

Newer Concepts of Breast-feeding

Sir,—Your contributor Dr. M. Witkin (March 31, p. 441) has once more made an attempt to bring new light to the question of breast-feeding which is developed from his previous attempt (*Arch. Pediat.*, 1939). Breast-feeding is a biological and physiological function of the female; the breast is but an appendage of the skin with highly specialized secretive tissues, and while the anatomical structure is discussed the physiological function of the gland is not mentioned. Any dairy farmer will state that in order to obtain good quality and quantity of milk it is essential: (1) to have a gentle sustained force to expel the milk; (2) to empty the gland as quickly as possible; and (3) to strip the gland completely at the end of milking. Here, then, we have a good precept to follow; if, as stated, there is some blockage to one or more of the ducts the obstruction will be overcome by the babe with a mouth specially formed for this work—a physiological method, better than manual expression, which can and does often cause trouble.

The assertion that both breasts should be employed is debatable. The breasts vitally secrete milk as the result of suckling, which increases the blood flow through the gland, the selective cells abstracting sugar, fat, and protein in that order; the chemical stimulus affects both breasts and prepares them for lactation, which is maintained by suckling; the absence of nervous control precludes reflex stimulation of the other breast, but the actual flow at the breast is determined by: (1) suckling (the greatest stimulant *per se* of lactation); (2) rate at which the child takes feed; and (3) stripping.

Feeding, as suggested, on both breasts does not allow either breast to function normally, correctly, and completely. Admitted that in the interval between feeds there is a slow production of a small quantity of milk, it is not until the babe has been at the breast for two minutes that the milk really begins to flow, not because of obstruction to one or more of the lactiferous ducts, but because of stimulation by suckling and the change from the resting to the secreting phase. During the period of suckling the various food substances are abstracted in correct proportion, and the final five minutes are essential for the stimulation of the gustatory juices of the feeder emptying the gland and obviating the necessity for manual expression of the milk. If both breasts are used the meal will not be balanced, but will have a high sugar and fat content with resultant signs of over-feeding and carbohydrate and fat dyspepsia, and neither gland will be stimulated or emptied completely.

It is not to be wondered at that increasing difficulty is being experienced in breast-feeding if both breasts are used. The majority of breasts are physiologically functioning correctly, and the number with pathological changes are exceedingly few, for these respond perfectly well to normal suckling. By all means let there be change for the better as our knowledge increases, but let due regard be paid to physiological processes, of which lactation is one of the simplest and best known, though often least understood. Pay a little attention to the knowledge of those whose livelihood depends on a good supply of milk—namely, the dairy farmer—and finally pity the poor twin who would have to have second feed in the proposed regime.—I am, etc.,

Leeds. R. O. Barber.

Ointment for Burns in Children

Sir,—Our object in sending this communication is to draw attention to a dressing that has been found to be of considerable use in the treatment of burns and superficial septic wounds in children. The ideal criteria for such an ointment are that: (*a*) the ointment should be bacteriostatic; (*b*) it should be an epithelial stimulant; (*c*) it should be analgesic.

Bearing these factors in mind we have evolved an ointment of the following composition: Sulphanilamide 5; urea 20; water-soluble base to 100. After experiment the base found most suitable was one of sodium alginate 10, liquid paraffin 10, water to 100, preserved with phenyl mercuric nitrate 1:600. The advantages claimed are theoretically that: (1) the sulphonamide fraction is enhanced by the destructive action of urea on *p*-aminobenzoic acid, normally present in serum; (2) there is a combined local analgesic and epithelial stimulant effect of the urea; (3) there is an anti-adhesive factor in the base.

In practice it is found that the ointment is inexpensive and does not deteriorate on storage and can be adequately sterilized. Clinically our practice has been to apply a thick layer of the ointment with a gauze dressing to the wound and for dressings to be done on every second or third day. In the cases so far treated epithelization has occurred rapidly, and it has been very noticeable how little pain has been experienced during the changing of the dressings. The ointment is suitable for issue in collapsible tubes for use as an emergency first-aid dressing for first-degree burns and superficial grazes.

We are aware that allantoin in combination with sulphanilamide has been used in similar conditions. The action of allantoin appears to be due to the formation of urea, but we are unable to satisfy ourselves that there is any advantage gained by the use of a more expensive and complex substance.

We should like to acknowledge the help and encouragement received from the honorary surgeons at this hospital.—We are, etc.,

Alec Rae, M.P.S.

The Hospital for Sick Children, Great Ormond Street.

Haemoglobin Tests for Blood Donors

Sir,—In common with the other large hospitals, a blood bank was started here just before this war broke out. After its inception we were struck by the fact that quite a number of anaemic-looking donors turned up to give blood, and were inclined to connect this with the not too infrequent fainting encountered. Consequently since Dec. 28, 1942, we have regularly carried out haemoglobin estimation (Sahli) on every donor before bleeding, and made it a rule never to take blood if the haemoglobin were under 85%.; or, in exceptional circumstances—e.g., at times of unusually heavy demand for blood—we would temporarily lower the standard to 80%.

Whether as a result of this selection, or for other reasons, we have practically ceased having fainting donors after venesection. We have now collected figures from 3,049 donors, and the tabulated results are as follows:

Hb %	Male		Female	
	Total No.	Percentage	Total No.	Percentage
45–49	1	0·1	3	0·2
50–54	—	—	3	0·2
55–59	—	—	5	0·3
50–64	5	0·4	15	0·85
65–69	7	0·55	27	1·55
70–74	16	1·25	63	3·55
75–79	16	1·25	165	9·3
80–84	96	7·5	518	29·4
85–89	233	18·1	534	30·2
90–94	358	27·9	285	16·15
95–99	277	21·5	114	6·5
100–104	195	15·2	28	1·5
105–109	65	5·0	3	0·2
110 and over	16	1·25	2	0·1
Totals	1,284		1,765	

This shows that a fair proportion of anaemic donors, many of them normal in appearance, may have been bled had we not taken the precaution described above. In fact, the figures show that if we had adhered rigidly to our higher standard of fitness for blood donation we should have had to reject over 25% of our subjects, and even on our lower standard the percentage would have been over 10. In actual practice we rejected approximately 15%.—I am, etc.,

Pathologist.

Selly Oak Hospital.

Sulphadiazine and Measles

Sir,—Some months ago I was called to see a child of 8 years and found her to be in the early stage of measles. The case was as severe as could be. The rash had developed during the preceding twenty-four hours and had in that time reached the confluent type. The child's temperature was 104.6° F., respirations were 30, accompanied by a distressing cough. There were no signs of pneumonia, but widespread rhonchi were present all over the chest. I suspected the probable onset of pneumonia, and as a precautionary measure put her on sulphadiazine. Owing to pressure of work I was unable to visit the case again until two days later, when I found the patient sitting up in bed looking cheerful and well. The rash had practically disappeared. The temperature and respiratory rate were normal and there was no cough. She was, in every sense of the word, convalescent. The course of events within 48 hours impressed me as dramatic.

Shortly afterwards there was an outbreak of measles at the public school under my care, and I decided to use sulphadiazine as a routine procedure in every case. I have now had the opportunity of analysing the results of the 43 cases which occurred during the term at the school. The conclusions I have arrived at are as follows: (1) The febrile stage averaged less than 48 hours. In the majority of the cases the temperature fell to normal within 24 hours. (2) The "illness" of the patient was of similarly very short duration. (3) The rash disappeared far more quickly than usual, as also the catarrhal signs. (4) All the cases were "well" within 2 days. (5) There were no complications.

I should be interested to know whether similar results have been experienced in other epidemics elsewhere, and, more important still, whether the type of measles has in any case been of this exceptionally mild order. Unless this is so, it would seem that the use of sulphadiazine in measles should be a routine procedure. Another very important consideration arises. Since the patient is clinically well and symptom-free within 2 or 3 days can the period of quarantine be considerably reduced proportionately?—I am, etc.,

Oxford. J. Frankland West.

Sulphonamide Therapy in Otitis Media

Sir,—Surely there can be little doubt of the value of sulphonamide therapy in early treatment of otitis media and prevention of mastoid complication. The dangers pointed out by Mr. A. R. Dingley (March 24, p. 422) of using a sulphonamide drug are less than the dangers of not employing one. In my experience in a busy country practice early employment cuts short the whole illness, lessens discharge, and, in very many cases, has saved paracentesis. One case of deafness which I noted was in a patient who was unable to tolerate the drug orally. I have not found deafness resulting from sulphonamide administration, and it has particular value in children.

The chief objection to sulphonamide therapy may be that the ear-nose-and-throat surgeon will intervene less often—acute mastoid infection is becoming much less frequent since the introduction of sulphonamides—and no doubt, with the extended use of penicillin, it is a question whether better results may be obtained.—I am, etc.,

Boreham Street, Sussex. C. Grahame.

Adrenaline in the Treatment of Malaria

Sir,—The use of adrenaline in the treatment of malaria, as advocated by Prof. M. Ascoli, head of the Clinica Medica of Palermo University, is of paramount importance and is rational for the following reasons: (1) It is easily administered intravenously. (2) It is harmless to the host, as it is already present in the body and *is not a foreign substance.* (3) It can be given to ambulant cases, and therefore there is no necessity, with the exception of malignant cases, to hospitalize men found to be suffering from malaria in all its stages. (4) The action on the spleen is immediate and dramatic.

Pioneer work has been done by Prof. Ascoli, but outside Italy little is known of this method of treatment. In Italy itself over two hundred pamphlets have been published by independent observers. Prof. Ascoli based his treatment on three facts: (1) The spleen contains the reserve supply of red blood cells. (2) The spleen is a contractile organ, and by contracting floods the general circulation with red cells whenever there is a call for additional oxygen, as in asphyxia, diminished atmospheric pressure (high altitudes, etc.), emotional states, fatigue, etc. (3) The stimulus is supplied by the medullary hormone of the suprarenal glands.

These facts were ascertained by experiments on dogs carried out by Barcroft and Binet. The contraction of the spleen after intravenous adrenaline is easily felt and takes under two minutes to complete. Relaxation is complete in about four minutes. The congestion of red blood cells in the spleen, where there is little or no plasma to protect them, exposes them to attack by the malaria parasites. These mature, sporulate, mature, sporulate again, without giving any indication at first of their presence, as there is no access of fever until the parasites reach the general circulation in sufficient numbers. If, in the treatment of malaria, the spleen is neglected the obvious result is that anaemia, more or less severe, sets in, while relapses occur every time the spleen, for one reason or another, is made to contract.

Relapses, therefore, after quinine treatment are easy to account for. It simply means that the spleen has been neglected. Relapses frequently occur in men immediately after discharge from hospital, the obvious reason being that they have been kept in bed for a period and drenched with quinine, etc. They have become soft and easily fatigued and they are discharged heavily clothed and carrying more or less heavy equipment. The fatigue produced calls for additional oxygen in the blood stream. The spleen immediately responds and in doing so lets loose a new army of parasites, many of them in the stage of sporulation, with the result that there is a sudden rise of temperature and all the signs and symptoms of a relapse.

It is an established fact that the natural protective power of the blood plasma is able to deal with large numbers of parasites circulating freely in the blood stream. It is claimed by many workers in this field, in addition to Prof. Ascoli, that, if the spleen is emptied daily for, say, thirty days, there is no need for any other form of treatment. Quinine is given only when there is a rise in temperature, and then only in comparatively small doses. However, combined operations, using adrenaline to drive the parasites out into the open and quinine at the same time administered orally, subcutaneously, or intravenously to aid in the destruction of the freed parasites, would appear to be the common-sense method of attack on malaria. Prof. Ascoli is now experimenting with injections of adrenaline three times a day so as to shorten the period of treatment from thirty days to ten or twelve, and is meeting with success. For this, of course, hospitalization is necessary, whereas the daily treatment is being carried out in the out-patient department of the Clinica Medica, Palermo University, where men, women, and children of all ages flock. Babies receive their injections in the jugular vein without any mishap and take the same doses as adults. Pregnant women also take the same doses, and here the use of adrenaline is particularly indicated, as it has no effect on the course of the pregnancy. To bring about the same results with quinine would certainly interrupt the pregnancy. Thirty-six healthy full-time babies were born last year in Palermo—the mothers having been treated with adrenaline intravenously with satisfactory results so far as the malaria was concerned and no harm to the babies.

In malignant or cerebral malaria the results are most striking. The theory is that the foci of malaria parasites in the capillaries of the brain are forced through to the venous circulation by the effect of adrenaline on the arterioles and the consequent general rise in tension and pressure. Several letters appeared in the *British Medical Journal* last year under the heading of "Cerebral Malaria." In each case the observer stated he began treatment *with an immediate injection of adrenaline.* He goes on to describe how he followed this up with intravenous quinine and gives all the credit for the sudden improvement to the quinine, whereas the fact is obvious that the injection of adrenaline gave the "knockout blow" and the quinine merely did the cleaning up.

There is some evidence, too, that a patient treated with adrenaline is immune from subsequent fresh infection, and this opens up a field for investigation and observation. In this connexion it is interesting to note that in 1942 a battalion of Italian infantry stationed in Sicily was moved to Sardinia. Soon after arrival about 80% of the unit went down with malaria. On investigation it transpired that all of the 20% who escaped had had malaria in Sicily and had been treated with adrenaline. It is not possible at this stage to explain this remarkable phenomenon. It may be coincidence, but, on the other hand, I have spoken with individuals who were treated over five years ago and they have had no sign of malaria since, no relapses, and no fresh infection, though they continued to live in a malarious area. The extreme importance of the phenomenon, if proved to be correct, is self-evident. It opens up untold possibilities and may well revolutionize our whole outlook on malaria. It may be that here we have the ideal prophylactic, and the day may come when everyone going to live in the Tropics will undergo a course of preventive treatment.

In conclusion, here is a form of treatment which is at once rational, simple, inexpensive, and safe. It can be carried out in the field and the saving in man-power is real, not only in the emergency of war but afterwards in civil life. If the spleen is thoroughly cleaned there can be no relapses. At the same time the saving in quinine and allied products will be colossal. The same, too, applies to post-war expenditures, as the need for hospitalization would be reduced to a minimum.—I am, etc.,

D. C. MacDonald,
C.M.F. Lieut.-Col., R.A.M.C.

Prophylactic Control of Malaria

Sir,—That "prevention is better than cure" has been well proved by the measures taken in the Australian and American Armies in the South-West Pacific to control malaria. In Burma and India the problem is more difficult, owing to the denser population in malarious areas and the impossibility of removing natives to other islands, as can be done in the Pacific. In the earlier stages of the war, in both theatres, the malaria rate was excessively high, but by the end of 1944 it had fallen in the Pacific to a figure only one-eighth of that on the Burma Front, and this was due to the very high standard of antimalaria discipline which came to be rigidly enforced in the Australian and American Armies, where it was laid down that the prevention of malaria in the field is not a function of the Medical Services but of the Command.

The general level of antimalaria discipline in our Burma operational areas is, however, lower than that of the Pacific Armies. A good example of the benefits obtainable by unremitting attention to detail was given by the O.C. of an Australian battalion, who showed that this discipline could be maintained even when his troops were in contact with the enemy, and he was able to reduce his unit's malaria rate to only a fraction of that of other units. This convinced the Australian military authorities of the practicability of reducing malaria in the field. After investigations carried on in the Assam–Burma area a series of experiments in two Australian research centres proved that malaria can be effectively suppressed by the administration of mepacrine. By this method all cases of malignant tertian are cured provided the drug is taken continuously for a month after leaving the malarious area, but benign tertian, with its greater tendency to relapse, requires a longer period for complete cure. A wide series of cases based on these findings showed 100% of recoveries. This improved malaria control is a distinct step in advance of the last great war, where large numbers of soldiers had to be temporarily invalided on "return trips," which became very popular.

It has been shown that mepacrine (atebrin) can be taken daily for an indefinite time, rendering the blood plasmodium-negative to mosquitoes. Other measures are also necessary. In anopheles-infected areas the orders are that gaiters must be worn, sleeves pulled down, and mosquito lotion applied to exposed parts of the skin. At night mosquito nets must be tucked under the mattress or weighted down. D.D.T. is being found to be the most effective insect-killing agent, and big quantities of it are being shipped to India.

In view of the large numbers of malaria-infected men arriving in Great Britain coming under the care of medical men many of whom have never been abroad, the question arises as to how the Indian and Pacific experiences in combating malaria can be best put into effect here. The usual methods of diagnosis by blood examination and treatment of an attack are well known, but the subject of periodic relapses and the eradication of gametocytes would appear to need further attention. Army Orders of February, 1944, prescribed a course of fourteen days, on the first two of which quinine is given, then five days of mepacrine, and two days without any antimalaria drug, followed by five days of pamaquin. Sufficient trial of the research work done in India and Australia has shown that the simpler procedure of placing sole reliance on mepacrine to prevent relapses is effective provided it is regularly administered, and the therapeutic discipline for this is the responsibility of the doctor at home. In the field on active service that same responsibility becomes the concern of the military authorities, who if they show any laxity are soon discovered by a rise in the malaria rate of the men in their command. Mepacrine, one tablet a day, can be taken for indefinite periods with no ill result.

Malignant tertian (otherwise subtertian malaria in our present faulty nomenclature), because of the rapid multiplication of plasmodia in the red blood corpuscles, can produce a dangerous infection requiring special treatment, whereas the benign forms can usually be brought under control in three days, but are more subject to relapse. But these relapses never occur if attention is paid to the details of prophylaxis. A summation of the present position is that although malignant tertian can be prevented and cured by mepacrine, benign tertian is prone to recur when the suppressive mepacrine is stopped.—I am, etc.,

G. D. G.

Hereditary Haemorrhagic Telangiectasis

Sir,—In his excellent account of a case of telangiectasia of the Osler type Dr. D. Cappon (March 31, p. 440) mentions that the patient has had a few of the red spots on the ends of her fingers, but does not state whether any were to be seen through the finger-nails. So far as I know, telangiectases (punctiform or small streaks) under the finger-nails are pathognomonic for telangiectasia of the Osler type, whether any familial history can be elicited or not. Anyhow, the diagnosis of telangiectasia of the Osler type can (though rarely) be made in the absence of any family history. In such cases either the information about the family history must be defective or else the patient must be regarded as the first in the family to manifest the condition (a gene mutation). Not long ago, for instance, a patient of this class was shown at the Royal Society of Medicine with typical telangiectases, some beneath the finger-nails, but with no family history of any similar condition.—I am, etc.,

London, W.1. F. Parkes Weber.

Neurological Symptoms in Infective Hepatitis

Sir,—In view of the attention being paid to neurological symptoms in cases of infective hepatitis, the following case may be of interest.

A female patient after two months in hospital developed polyneuritis. The peripheral paralysis spread upwards, and threatened the respiratory muscles. The specialist's report was: "Vomiting, illness, paralysis. Toxic hepatitis and polyneuritis (virus infection). Slight jaundice. Muscular wasting, and loss of power in limbs and trunk. No tendon jerks. Contraction of ankle flexor groups."

Using microchemical methods, we searched for any toxin. The patient was given charcoal, and the charcoal subsequently recovered from the faeces and examined. Two known toxins could have caused the condition—coniine and hypoxanthine. Neither could be found, but there was a profuse growth of *Cl. welchii.*

The patient then improved, and then relapsed. Another examination was negative. She then died. From the liver an alkaloidal base was isolated which gave the following reactions: It had a penetrating, irritant odour. Heated with sulphuric acid and pot. bichromate, it gave a smell of butyric acid. There was no precipitate with platinic chloride in the cold, but an opacity appeared on heating. The watery suspension was muddy, and cleared on heating. The base was liquid, and gave a purple colour with alloxan. It gave rhombic plates, with notched edges, with Reinicke's salt. These are the reactions of the pyridine derivative, coniine. The boiling-point was higher than that of the pure alkaloid.

It has been thought that coniine can be formed from urea and butyric acid. *Cl. welchii* is a producer of butyric acid. It is possible that this neuritis was due to a toxin, of the nature of coniine, formed in the patient's liver.—I am, etc.,

Wakefield Laboratories, Bethlem Royal Hospital. C. Lovell.

Fulminating Gas Gangrene

Sir,—In order to be able to draw the correct conclusions from the case described by Lieut.-Col. C. J. Cellan-Jones and Major E. M. Griffin (April 7, p. 482) the matter requiring clarification is the term "thorough wound toilet." Everything hinges on this. It is imperative to know whether the wound was really widely opened up by extending the original wound and explored thoroughly in its full extent, fascial planes widely opened, foreign material removed, and every bit of dead and damaged tissue excised. We have had a number of localized gas gangrenes in battle casualties, and in every case the primary operation was inadequate, although every one has been described as a wound excision. Pending further information, no criticism is offered, but in a wound operated upon within 8 hours the avoidance of gas gangrene is entirely a surgical problem.

No dead tissue, no gas gangrene.—I am, etc.

St. Margaret's Hospital, Swindon. F. Louis, F.R.C.S.

Estimation of Heat Radiation in Clinical Practice

Sir,—The question raised by Dr. C. B. Heald (March 24, p. 421) concerning the effect of an interposed layer of lint in the application of radiant heat is an interesting and important one, but, unfortunately, it is one of those to which the physicist cannot provide a simple answer. This is the reason why it was omitted in our recent paper on the estimation of heat radiation (Dec. 23, 1944, p. 811). The problem has already been discussed to some extent in an earlier paper (Jan. 16, 1943, p. 66), when we had to deal with the case of the patient in the heat cradle who is wrapped in a blanket. The interposed material will be warmed up by the radiation from the radiation source and will act as a secondary radiator. The secondary radiation is of longer wave-length, depending on the temperature of the blanket. It is, however, likely that a good deal of heat is transferred by conduction through the narrow air space between blanket and patient, and this effect renders the whole problem rather complex. Experiments to determine these factors separately are in progress, and the results will be published in due course in the *British Journal of Physical Medicine.*

The more specific question of how much of the original radiation from the treatment source penetrates the interposed material can already be answered. Using the same radiation flux ($\sim$1 cal./cm.^{2}/min.) we have determined the absorption in various materials of the radiation from a tungsten filament lamp (radiation maximum at $\sim$1.5 μ) and an electric fire (radiation maximum at $\sim$3 μ). In the following table the percentage of original radiation flux reaching the skin through the various interposed materials is given for these two sources.

Source	Lamp	Fire
Lint	31%	24%
Blanket	25%	19%
Cotton sheet	48%	30%
Linen sheet	44%	30%
Towel	27%	22%

It must be emphasized that these values are rough ones, indicating only the order of magnitude of the transmitted radiation flux. Nevertheless it appears from the results that the shorter wave-lengths have a somewhat greater penetration. Secondary radiation and heat conduction were excluded in these experiments.—I am, etc.,

Radcliffe Infirmary, Oxford. K. Mendelssohn.

Ovariotomy or Caesarean Section?

Sir,—Mr. Malcolm Donaldson (April 7, p. 495) rightly emphasizes good antenatal treatment in the early months of pregnancy as the solution of this problem. This implies the attendance of the patient at the first opportunity; it is easier to diagnose ovarian cyst in the early months than in late pregnancy, and a complete examination must be made at the first visit, including pelvic examination. In the clinic with which I am associated both of these requirements are fulfilled. Uncomplicated cases are not booked after the sixteenth to eighteenth week and all new patients are examined bimanually. In 1944 there were 1,275 bookings and six cases of ovarian cyst were seen. In each case ovariotomy or ovarian cystectomy was done. None of these patients suffered interruption of pregnancy as a result of the operation, and most of them have since been delivered.

It is my opinion that the practice of removing ovarian cysts in early pregnancy is not widely followed because: (1) The diagnosis of symptomless ovarian cyst is made, as a rule, by bimanual examination and not by abdominal palpation alone.

Routine bimanual examination is often not done in hospital clinics, less often in child-welfare clinics, and practically not at all in general practice. (2) There is an unfounded fear that ovariotomy in early pregnancy may cause abortion. Caverley, in 1931, reported an abortion rate of 11.4%, but from my own experience this figure appears to be too high. I have records of 18 cases without a single one of abortion. Progesterone is given before and after operation, and it may be that this safeguard explains the difference.

With regard to ovarian cyst complicating labour, I feel that some mention should be made of vaginal manipulation directed towards dislodging the cyst. With anaesthesia and the Trendelenburg position it may be remarkably easy, and with reasonable care is not dangerous. Failure to displace the cyst, in my opinion, calls for lower-segment Caesarean section followed by ovariotomy, as with Bonney and Marshall I consider this treatment to be more humane and less risk to the patient.—I am, etc.,

Sunderland. FRANCIS J. BURKE, M.R.C.O.G.

"Predisposition" to War Neuroses

SIR,—It is being emphasized with increasing frequency in articles on war neuroses, and taken very much for granted as an established fact (e.g., S. I. Ballard and H. G. Miller, *Journal*, March 3, p. 293; L. Minski, *Journal*, March 31, p. 444), that predisposition to breakdown under war conditions can be correctly estimated from the occurrence of nervous and mental illness in the family and personal history of the patient, and (Minski) from a poor work record. It is a matter of some importance to point out that this is largely assumption and is not justified in the present state of our knowledge. It may later be proved to be the case; psychiatry would be a simpler science if the principle implied were confirmed, but it has certainly not been substantiated. I have shown elsewhere, from my experience in the last war, that many individuals who had attacks of neurotic disorder and others with a bad family history made excellent soldiers and sometimes won decorations for bravery. My experience in the present war has added further corroborative evidence to this observation. So far as a good work record is concerned, it may of itself denote freedom from actual breakdown, but it not uncommonly is, for example, an indication of obsessional over-conscientiousness and inferiority.

Clearly, before the significance of family history and previous nervous illness can be assessed, a control investigation will have to be undertaken to show what proportion of soldiers who have been stable and successful under active war conditions reveal such psychiatric incidents in their personal and family records.—I am, etc.,

London, W.1. FREDERICK DILLON.

Once Again Barotrauma

SIR,—I am indeed sorry for your reader who, interested in barotrauma, wishes to know more about it. He must by now be in a state of advanced bewilderment. After a good deal of controversy, he was told in an annotation (Feb. 10, p. 190) that the condition was definitely not inflammatory. Later, he may have read my letter (Feb. 24, p. 276) pointing out that if we accept your annotator's well-founded opinion on the absence of inflammation, the term "otitic" is just as bad as the old "aero-otitis," now generally discarded as misnomer. He may later still (March 10, p. 346) have been pleased by the fairness and good sense of your annotator, who, stimulated by my letter, replaced "otitic" by aural.

So far, so good; but now it is all changed again! Air Cdre. Dickson in his recent letter (March 24, p. 423) expresses the view that whereas "otitis" implies something infective, "otitic" does not do so, and that there is enough inflammation to the condition to justify retaining the term "otitic" anyway. Moreover, up to now the reader has learned that actual rupture of the drum was a rather rare complication of barotrauma. The second paragraph of Air Cdre. Dickson's letter suggests it to be of regular occurrence. What a wealth of diverging views!

Duly influenced by the opinion of the R.A.F. expert, your reader will be apt to conclude that the process is an inflammation after all. The surprising part about this opinion is, however, that it is plainly at variance with the view of the pathologist of the team, Wing Cmdr. Colin Campbell, who in his address at the R.S.M. (Dec. 3, 1943) and as co-author of Air Cdre. Dickson's paper (*J. Laryng.*, 1943, 58, 483) made such a convincing case for the absence of inflammation in the lesion. Has Wing Cmdr. Campbell failed to convince Air Cdre. Dickson? Or has he himself changed his opinion?

At least the issue now is clearly set: if the condition is inflammatory, your annotator as well as myself are wrong, and "otitic" has the right to stand; if not, "otitic" should go. However, may I in order to cut short an argument which can only lead to "it all depends on what you mean by inflammation" propose: if Air Cdre. Dickson would leave his "acute otitic," I will drop the "pressure syndrome," and we all meet, with your annotator, on "aural barotrauma" from now onwards.

One more point. It is not only the name of the thing which is controversial. Clinically, too, barotrauma will continue to be a problem as long as the essential preventive measure is neglected—i.e., to teach the airman to perform himself Politzer's method. To train him in Valsalva's experiment is unsatisfactory. Barotrauma starts when the Valsalva fails. The Valsalva fails soon, and as soon as it fails the mere attempt is harmful. For reasons beyond the scope of this letter, the unsuccessful Valsalva aggravates the block at the pharyngeal end of the tube, and is thus inducive to barotrauma. The case for politzerization is that it will succeed in most instances in which Valsalva fails, and that it can do no harm. The scheme, with a suitable bag, is well practicable. I know a number of pilots as well as high-altitude passengers, whom, after barotrauma, I have taught to use the Politzer bag and who have been clear ever since, and do not care to board a plane without it. Of course, Politzer's method may not be feasible for the fighter pilot forced to lose height suddenly in the pitch of battle, but I understand that the great majority of cases arise out of much less momentous incidents.

The routine use of Politzer's method by the airman himself will prevent barotrauma, provided nobody suffering from a cold or sore throat is allowed to fly—i.e., nobody in whom politzerization on the ground might be impossible or contra-indicated. The Politzer bag should, I think, form part of every airman's kit, and the instruction in its use a short (it takes only ten minutes) though integral part of his training. High-flying civil aviation, too, should give the matter their attention. On most airfields a doctor is available. Politzerization should be obtainable for those passengers whose ears feel blocked on landing. It could be easily arranged for, to the immediate relief and delight of the passengers and to the prevention of airborne deafness. *Sic finit* barotrauma, until the pressure-conditioned aircraft will make it altogether extinct.—I am, etc.,

St. James' Hospital, S.W.12. A. B. ALEXANDER.

SIR,—Air Cdre. E. D. Dalziel Dickson's letter (March 24, p. 423) and that of Dr. R. M. S. Matthews (March 31, p. 458) prompt me to submit another term for the condition which they call "otitic barotrauma"—namely, "anisobaric otitis."

"Inflammation," as Air Cdre. Dickson states, is an inevitable sequel of the forces producing the disability, and because this is the most important sign, varying in degree from slight capillary dilatation to that associated with rupture of the ear-drum, "otitis" is reasonably descriptive of the condition, whatever the qualification attached to it. "Anisobaric otitis" is euphoniously self-explanatory—an inflammation of the ear caused by unequal air pressures applied to it. Like "otitic barotrauma," it is wholly *Greek* in derivation.—I am, etc.,

T. A. JAMES.

Shall We Nationalize Medicine?

SIR,—In your issue of April 7 (p. 497) Lord Horder asks: "Shall we nationalize medicine?" If we *had* to choose one of two alternatives: "Shall we nationalize medicine?" or "Shall we commercialize medicine?" I wonder which Lord Horder would consider the lesser evil?

Since the last war medicine has undoubtedly, to a very great extent, been commercialized. In places it has become a sheer commercial "ramp," and with the almost complete disappearance of etiquette, as it was understood in my grandfather's time, the relationship between large numbers of the "medical trade" has become shocking.

I am open to correction, but I believe I am right in saying that the friendly spirit of co-operation and good will which exists to-day between Service members of the profession, where all "cut-throat" competition and commercialism, fee-hunting, etc., are removed, suggests that in a *first-class* State medical service (in which each one of us had an assured position and an allotted task) better relationships might exist among the medical fraternity than is the case to-day. We might even then learn (1) to unite, (2) to cease fighting one another, and (3) to combine in order to work constantly for improved conditions both for ourselves and for our patients.—I am, etc.,

Hassocks, Sussex. CHARLES A. H. FRANKLYN.

SIR,—Lord Horder (April 7, p. 497) says the word "politics" is used in two senses—namely, civil administration and partisan influence. I agree. Are not these two senses better understood if we read "efficiency" for civil administration and "self-interest" for partisan influence? By "efficiency" I understand the most efficient service possible under the circumstances of to-day—i.e., having regard to medical personnel available, the number and distribution of persons to be cared for, the financial and other resources, etc. Medical efficiency is a *practical* problem. By "self-interest" I mean the economic, professional, and other self-regarding interests that actuate all social groups, like the "profession," the "people," the "State," etc. Medical interests constitute a highly emotional problem.

On this basis it would seem that the questions to be asked are two: (1) How can the profession of medicine best be organized to give the "most efficient" service? (2) How can the profession *and other "groups"* learn to put the interests of society before and not after their "self-interests"? To ask this last question is *not* to answer it. I agree with Lord Horder that if we create a service into the conduct of which partisan self-interest can easily be injected, then no matter how "efficient" that service may be, it will soon be a bad service. I agree with Prof. Ryle that to oppose alterations in the service just because self-interest seems to dictate opposition would be to create a most serious crisis in the profession (of course, we believe we shall *never* do that!).

I am sure we ought to seek to separate these two questions in our minds and take care not to think about them on the false assumption that administration and partisanship are both the same thing—namely, "politics."

As a G.P. I believe that the proposals advanced by the B.M.A. are, on the whole and in general, the best and soundest solution of both the practical and the emotional problems that has yet been made. Thoughtful practitioners should support them in every possible way—political and otherwise.—I am, etc.,

Worcester HOWARD E. COLLIER.

Civilian Mass Radiography

SIR,—Let us hope that your leading article on civilian mass radiography (April 14, p. 521) will receive proper attention from the authorities who are to be entrusted with the launching of this scheme. One has been accustomed to regard reports issuing from the Medical Research Council as bearing the stamp of true scientific authority; but in their recent report on mass miniature radiography one's trust is rudely shaken. It seems almost unbelievable that the M.R.C. should recommend that, to quote the words of your leading article, "in doubtful cases the medical directors of the unit must often decide *from one interview and radiograph*" (the italics are mine) "not only whether the subject has pulmonary tuberculosis, but also whether the disease is active." As you rightly observe, "anyone who has had experience in a chest clinic will realize the absurdity of this suggestion"—and also, might I add, the danger.

Early symptomless tuberculosis has been the subject of correspondence and criticism on several occasions in the past, but once a novel measure has caught on with the public authorities (in this case the Services—Navy, Army, and Air Force), it is apt to run riot. In the *Journal* of Aug. 24, 1940, there appeared an article on mass radiography by Lieut.-Col. E. L. Cooper, Assistant Director-General of Medical Services, Australia, which evoked letters criticising his conclusions. A letter from Sir Henry Bashford (Sept. 21, p. 395) ended with these words after acknowledging the value of mass x-ray examination of recruits for the Army: "But it is profoundly to be hoped, if the process is to be extended to the normal school, industrial, and social life of the country, that the utmost care will first be taken to learn and assess what is in fact prognostically significant in these x-ray findings; and to avoid unnecessarily labelling and perhaps segregating—with possibly dire psychological consequences . . . new hosts of young men and women as cases of pulmonary tuberculosis." There was also a warning letter from J. F. Brailsford (Oct. 5), a radiologist of repute. In a letter (Nov. 2) I ventured to call attention to the wise words with which Lieut.-Col. Cooper himself had concluded his article: "This paper must close upon a note of caution. There has been much criticism of the microradiographic method of diagnosis. . . . It is not the opposition which is to be feared . . . ; a greater danger is that of the too ardent advocate. . . . *No one should be labelled tuberculous on the unsupported evidence of a 35-mm. film*," to which I added with some trepidation, "nor even . . . on the *unsupported* evidence of a full-size film."

In the *Journal* of May 8, 1943 (p. 565), the subject was again revived, in the form of a review of the results of mass radiography of 7,500 cases in the R.A.F. by Fl. Lieut. A. G. Evans, which again drew letters of criticism from J. F. Brailsford and Z. P. Fernandez (June 19, p. 770). In July of the same year correspondence on symptomless early tuberculosis in which the diagnosis was based solely on x-ray evidence again became the subject of discussion, following an article by Margaret C. Macpherson, of the Research Department, Brompton Hospital (July 24, p. 98), who advocated treatment of such cases in adolescents by artificial pneumothorax. Letters criticizing this view followed from A. Niven Robertson (Sept. 18), Price Williams and F. R. Walters (Oct. 9), and from myself (Nov. 13), when I ventured to put the following as the critical question to be answered: "Can x-ray examination alone prove the existence of a tuberculous focus in its earliest phase in the absence of all clinical signs and symptoms?" I went on to say: "We have been told by expert radiologists recently that though a shadow may be definitely diagnosed as tuberculous in origin, *it is often impossible to say whether it indicates active or merely obsolescent tubercle*, and that a shadow seen to-day may be gone a few weeks later."

These criticisms all came from men who had special experience in tuberculosis work. Of one thing I feel sure: mass radiography, *unless under the control of both experienced clinicians and experienced expert radiologists equipped with first-class apparatus*, will result in the addition of large numbers to the ranks of those unfortunates who have been wrongly labelled tuberculous.—I am, etc.,

Southborough, Tunbridge Wells. E. WEATHERHEAD.

Final M.B. of London University

SIR,—I fully concur with what has been said by Dr. D. S. Porter (March 3, p. 310) and Dr. H. B. Hewitt (March 17, p. 387) about the new regulation for the Final M.B. of London University, and wish to support whole-heartedly their appeals.

I am among those unfortunates who have been "bunkered" in Part III by the old regulation during the war. Why the new regulation should apply only to those candidates who are now beginning to sit their finals and not to their wartime predecessors is beyond my comprehension. If anything, it should be vice versa! The general atmosphere and conditions prevailing now (and for some time past) are certainly more conducive to preparation for and sitting an examination than they were earlier in the war.

Obviously, the regulation is grossly unfair, and it would indicate some consideration for those of us in the Forces if it were extended to include the earlier wartime candidates. I should be most grateful if you would publish this letter, and I sincerely trust that the authorities concerned will give the matter their serious consideration.—I am, etc.,

TREVOR DAVIES,
Surg. Lieut., R.N.V.R.

Obituary

SIR JAMES BARRETT, K.B.E., C.B., C.M.G., LL.D., M.D., M.S., F.R.C.S., F.R.A.C.S.

The death of Sir James Barrett, briefly announced last week, removes an outstanding figure from the profession in Australia who gained distinction in many fields of endeavour. No one played a more active and pervasive part in the modern development of Melbourne in its educational, medical, and public affairs. He was consulting surgeon to the Victoria Eye and Ear Hospital, consulting oculist to the Royal Australian Navy, and honorary secretary of, and a leading spirit in, the Victorian Bush Nursing Association. He presided over the Annual Meeting of the B.M.A. in Melbourne in 1935 and a year later was elected Chancellor of the University, after holding office as Vice-Chancellor since 1931.

[Photo by Cato, Melbourne

James William Barrett was born on Feb. 27, 1862, eldest son of James Barrett, M.D., a native of Banbury, Oxfordshire, who qualified in medicine in London, and after acting as doctor on an emigrant ship to Melbourne remained there and became physician to the Alfred Hospital. J. W. Barrett began his education at Melbourne Grammar School and matriculated at the University at the age of 15. After graduating M.B., B.S., and two years as R.M.O. at the Melbourne Hospital, he came to England, took the M.R.C.S. in 1884, and during the next two years worked as demonstrator in physiology at King's College, London, clinical assistant at Moorfields Eye Hospital, and assistant surgeon to the Western Ophthalmic Hospital. He had passed the Final F.R.C.S. examination, but could not be granted the diploma before his 25th birthday. On returning to Melbourne Barrett proceeded to the degrees of M.D. and M.S., became demonstrator of physiology in the medical school of the University, and soon after arrival was appointed to the visiting staff of the Victoria Eye and Ear Hospital; he resigned that post in 1913 on accepting election as ophthalmologist to the Melbourne Hospital. For many years he lectured on the physiology of the special senses in the University.

During the early part of the last war he served as A.D.M.S., Australian Forces in Egypt, and then as consulting oculist and aurist to the Egyptian Expeditionary Force with the rank of lieut.-colonel, first in the A.A.M.C., later in the R.A.M.C. His valuable war services were recognized by the award of the Order of the Nile (3rd Class) in 1916, and the K.B.E. and the C.B. (Military Division) in 1918; he had received the C.M.G. in 1911. After the end of the war he became consulting eye specialist to the Royal Australian Navy and oculist to the Royal Victorian Institute for the Blind and to the Marine Board of Victoria. In 1927 he was a founder and original Fellow of the Royal Australasian College of Surgeons.

Sir James Barrett's extra-professional interests were remarkably wide and varied; a list of the presidencies and chairmanships he had held would take up many lines of print. There seem to have been few good causes or public enterprises in Victoria, or indeed in the Commonwealth, which went without his active support. His pen was never idle. Many of his articles on public health, education, electoral reform, and Imperial and Australian politics were written for the *Melbourne Argus* and afterwards reprinted in two volumes. His informal reminiscences appeared seriatim in the *Melbourne Herald* in 1938. Twenty years earlier he published two books—*Twin Ideals: An Educated Commonwealth* and *The Australian Army Medical Corps in Egypt*, the latter written in collaboration with Lieut. P. E. Deane. In 1919 Barrett published *War Work in the Y.M.C.A. in Egypt* and *A Vision of the Possible: What the R.A.M.C. Might Become*; he also wrote *The Diary of An Australian Soldier* and *Save Australia*. He represented the B.M.A. in Australia at the Winnipeg Annual Meeting in 1930, and on the occasion of receiving the honorary degree of LL.D. from Manitoba University it was said at the Congregation: "His writings, which have been extensive, deal in great part with medico-sociologic and medico-military problems. Eminent as a surgeon, soldier, author, and philanthropist—a great Australian whom a sister Dominion delights to honour." His Presidential Address at the Melbourne Annual Meeting was an interesting and suggestive statement of hospital problems as they presented themselves in Australia and New Zealand, in which he drew illuminating and instructive parallels and contrasts between the hospital systems in those two Dominions and in Great Britain. He had something of real value to say to the visiting members, and said it with clarity and emphasis.

E. LAMING EVANS, C.B.E., M.D., F.R.C.S.

We regret to announce the death on April 6 at Sidmouth of Mr. Evan Laming Evans, emeritus surgeon to the Royal National Orthopaedic Hospital, consulting surgeon for orthopaedic cases to the West End Hospital for Nervous Diseases, and consulting orthopaedic surgeon to the British Postgraduate Medical School, Hammersmith.

He was born on Sept. 3, 1871, youngest son of Worthington Evans, and was educated at Eastbourne College and Trinity College, Cambridge, where he graduated B.A. in the Natural Sciences Tripos of 1892. He took his clinical course at St. Bartholomew's Hospital, and after qualifying as M.B., B.Ch. Cantab. in 1896 was house-surgeon there, and won the Raymond Horton-Smith Prize for his M.D. thesis in 1901. During the South African War he served on the medical staff of the Welsh Hospital, receiving the Queen's Medal with three clasps, and on his return to civil life made orthopaedic surgery his career. He was for many years a member of the visiting staff of the Royal National Orthopaedic Hospital and surgeon to the Royal Surgical Aid Society, consultant to the Industrial Home for Crippled Boys and to King Edward's Hospital, Ealing.

Laming Evans joined the B.M.A. in 1896, was vice-president of the Section of Orthopaedics at the Bradford Meeting in 1924, and president of that Section when the Association met at Winnipeg in 1930; he was also a past-president of the Orthopaedic Section of the Royal Society of Medicine and of the Harveian Society of London. He was created C.B.E. in 1920. His published writings were all on orthopaedic subjects and included an essay on astragalectomy for the *Robert Jones Birthday Book* and a paper on late results of the manipulative treatment of congenital dislocation of the hip, printed in the *British Journal of Surgery*. His elder brother, the Right Hon. Sir Laming Worthington Evans, Bt., who died in 1931, held a succession of Ministerial posts in the Government and was Secretary of State for War for two periods.

Mr. A. ROCYN JONES writes:

With the passing of E. Laming Evans almost the last link between two periods of orthopaedic surgery is removed. He began his training in orthopaedics at the old Royal Orthopaedic Hospital in Hanover Square—the building itself has long since disappeared—and in a day when most of the work of an orthopaedic surgeon consisted in manipulation and tenotomy, for the attack on deformity by open operation had scarcely begun. Indeed, he was fond of relating with what patience his masters would unfold an intractable club-foot, only calling to their aid the ingeniously contrived Scarpa shoe—a splint which is but a name to-day and is undeservedly discarded. He witnessed the wide extension of orthopaedic surgery and took a hand quite early in the development of its operative procedures. But to the end he retained the impress of his early training, for he would, by patient repeated manipulation alone, produce an astonishingly good correction of a badly deformed foot where a less-disciplined junior would seek relief by open section. The same capacity was manifest in his treatment of congenital dislocation of the hip, where by manipulative skill and meticulous after-care he produced results which were unsurpassed. In open operations he was careful but not adventurous, although he took a boyish delight in practising any new procedure; and his enthusiasm never waned. He achieved a peculiar success with Whitman's operation for the difficult paralytic calcaneo-cavo-valgus disability: his results were so consistently good that he adhered to this operation when it had lost favour with other surgeons.

Never was a surgeon more conscientious in the discharge of his hospital duties—he was chairman of the medical board for several years—and especially in the operative treatment and after-care of his patients. It was perhaps because of this devotion that he was apt to be ruffled by the occasional perverse indifference of someone he was trying to help; in such a mood he could be formidable. His crowded clinic at the Royal National Orthopaedic Hospital was eloquent testimony to the high regard for his work, and many of his house-surgeons will read of his passing with deep regret and will reflect upon how much they owe to him for guidance in the principles of orthopaedics.

A. W. SHEEN, M.S., F.R.C.S.

Prof. G. **Grey Turner** sends the following tribute:

The death of Prof. A. W. Sheen of Cardiff when in full work in his 76th year will be very much regretted by his many friends, for he was a man of striking personality with a great gift for companionship. During the earlier part of his career he was particularly interested in those conditions which are likely to be met with among the population of an industrial area, and, like other surgeons, was trying to evolve the best and most practical technique. With his experience of operating in the homes of the people and in the smaller hospitals, he had a good deal to do with the development of surgery in South Wales. During the 1914–18 war he commanded the 34th (Welsh) General Hospital, first at Netley and later in India. In that capacity his experience with the Imperial Yeomanry Field Hospital in the South African War stood him in good stead. At the end of hostilities Sheen acted as consulting surgeon to the war hospitals of India and did much for the rehabilitation of the wounded. This question continued one of his great interests and afterwards he did much to promote its study in connexion with industrial injuries. After returning to this country Sheen settled for a time in London, where among other activities he worked at the Shepherd's Bush Orthopaedic Hospital. But his most fruitful period began when he was chosen professor of surgery and director of the surgical unit of the Welsh National School of Medicine in Cardiff. His work there lay very largely in the organization of the new venture. As professor he was very active and strove hard to justify the creation of the special surgical unit at the Cardiff Infirmary. The early days were troublous; but, as a result of his clear conception of the course that was in the best interests of the development of such a school and his determination and tenacity, he did a very valuable piece of work. Though in this direction he earned such a creditable record it can only be known to a few that his plans for the future were on the grand scale.

Sheen was never satisfied with anything but a very high standard of endeavour. Some years before the war he inspected the surgery examinations in the University of Durham, and all were impressed by the thoroughness which he brought to that task. In private life he was most hospitable and loved to entertain those associated with the work of the department of surgery, and the outside examiners especially will remember the delightful time when they were guests in his house. He was very systematic and painstaking and master of university routine, though he sometimes inveighed against the restrictions and narrowness of traditional practice. Sheen was fond of travel and was always welcome on the visits of the Moynihan Club and at the congresses of the International Society of Surgery. But above all else he loved companionship, was a good talker, told a story with due emphasis, and always had a ready jest to point a moral. He was very kind to young people and fond of little children. Sometimes a rather brusque dictatorial manner was repellent, or his breezy style gave the impression of flippancy, but these were only poses which disguised sincerity and a generous warm heart.

The following well-known medical men have died abroad: Dr. **Sokrates Lagoudakis**, the eminent leprologist, at Alexandria, aged 82; and Dr. **Graeme Monroe Hammond**, who had been a leading New York neurologist, aged 86.

No. 9 of the *Medical Chronicle*, published in Moscow by the U.S.S.R. Society for Cultural Relations with Foreign Countries, consists of a number of short articles of professional interest, and makes two announcements. One is that the Saratov Institute "Microbe" recently marked its 25th anniversary. This institution is carrying on scientific work in microbiology and epidemiology in the south-east of the U.S.S.R. With its practical work, which consists in promoting and combating epidemics, the Institute combines extensive scientific research and the training of medical and sanitary officers in the control of malignant infections. The other announcement is of the 70th birthday of Prof. Nikolai Semashko, director of the department for organizing health protection and general hygiene at the 1st Medical Institute in Moscow, and also chief executive officer of the U.S.S.R. Hygiene Society.

Universities and Colleges

UNIVERSITY OF ABERDEEN

The University Court on April 11 was informed that the King had approved an Order in Council for the establishment of the Crombie Ross Chair of Mental Health in Aberdeen University. Gifts of £10,000 from the Crombie Ross Benevolent Fund and £5,000 by Dr. John A. Ross for the foundation of this Chair were announced in 1944.

At a graduation ceremony on March 29 the following medals and prizes won in the Faculty of Medicine were awarded:

Chanock Gold Medal in Anatomy: James B. Johnston; *proxime accessit,* Alexander J. Watson. *Dyce Davidson Gold Medal in Materia Medica:* Douglass W. Taylor. *Fife Jamieson Memorial Gold Medal in Anatomy:* Gordon L. Ritchie and Alexander J. Watson (equal); *proxime accessit,* James B. Johnston. *Lizars Gold Medal in Anatomy:* James B. Johnston; *proxime accessit,* Gordon L. Ritchie. *Struthers Gold Medal and Prize in Anatomy:* Gilbert F. Hamilton, M.B., Ch.B.

UNIVERSITY OF EDINBURGH

At the graduation ceremonial on Jan. 20 the degree of M.D. was conferred, *in absentia,* on Lieut.-Col. J. M. Matheson, R.A.M.C. Through a printer's error the name appeared as J. M. M. Batheson in the *Journal* of Feb. 3 (p. 169).

UNIVERSITY OF WALES

Welsh National School of Medicine

The following candidates have satisfied the examiners at the examination indicated:

M.B., B.Ch.—*Surgery:* W. H. Beasley, B. L. Crystal, G. K. Davies; Hannah P. Evans, L. A. J. Evans, M. Evans, Joan Guy, P. G. Jagger, Jane W. James, W. J. Jenkins, D. G. Jones, D. R. Lewis, Joy A. MacGregor, Barbara D. S. Marshall, J. Matthews, D. B. Price, Gwladys M. Sewart, Glenys M. Thomas, D. Tooms (with distinction), L. L. R. White, Catrin M. Williams, D. M. Williams, Roberta Williams, W. O. Williams. *Obstetrics and Gynaecology:* A. J. Barry, E. M. L. Evans, W. J. Jenkins, D. O. Lewis, Isobel F. A. Mitchell.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the College held on April 12, with the President, Sir Alfred Webb-Johnson, in the chair, the following were elected Fellows under the Charter which permits the Council to elect annually to the Fellowship, without examination, two Members of 20 years' standing: H. Guy Dain, M.D., Chairman of Council, British Medical Association, and Brig. Harry Stobie, Professor of Dental Surgery in the University of London and Dean of the Royal Dental Hospital.

Mr. R. P. Scott Mason was elected a member of the Court of Examiners for three years from May 10.

The Jacksonian Prize for 1944 was awarded to Lieut.-Col. Kenneth W. Starr, F.R.C.S., for his essay on the causation and treatment of delayed union of fractures of the long bones. The subject for the prize for 1946 will be "Traumatic Aneurysm." Mrs. Lilian Lindsay, L.D.S., Librarian of the British Dental Association, was awarded the John Tomes Prize for 1942–4 for her outstanding research work in the bibliography of dental science. The first award of the Begley Prize was made to Peter Charles Conlon of the London Hospital.

It was decided to institute two courses a year of lectures on surgery, beginning in the autumn of 1945. Lecturers will be selected by invitation. Fellows and Members of the College will be admitted free and there will be an admission fee of two guineas for others for each course of 12 lectures.

The Council confirmed its previous intention to grant a higher diploma in dental surgery, which will be subject to obtaining power to revise the Charters. It is proposed to entitle the diploma "Fellowship in Dental Surgery."

Mr. Eardley Holland was re-elected the representative of the College on the Central Midwives Board; and Air Vice-Marshal Geoffrey L. Keynes was nominated for reappointment as an external examiner in surgery for the Faculty of Radiologists.

Diplomas of Membership were granted to W. McC. Anderson, D. J. Atherton, and R. S. Jones.

Diplomas in Child Health were granted jointly with the Royal College of Physicians of London to the following successful candidates:

Gwladys V. S. Aldridge, Florence H. Auckland, Annie C. Brown, E. A. Cachia, Marjorie E. Claye, Kathleen M. Corbett, P. D. A. Durham, P. G. Finch, J. H. Gibson, H. McC. Giles, D. B. Jelliffe, E. Kost, Josephine M. Lord, Katleen M. Miller, Dorothea B. I. Montgomerie, Moira K. E. Reaney, D. C. Thursby-Pelham, E. Tuckman.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

The following have been elected to the Fellowship of the College: G. S. Adam, Caroline A. Elliott, E. A. Gerrard, A. M. Hill, J. J. Kearney, R. J. Kellar, Alice M. Kenny, W. K. McIntyre, B. T. Mayes, H. K. Pacey, F. Stabler, F. R. Stansfield, G. A. Thompson, The following have been awarded the Diploma of the College: Isabel H. M. Blyth, J. T. Carson, H. J. A. Conte-Mendoza, G. K. Emsley, J. L. Farmer, J. J. Handler, D. Heap, A. Henderson, M. Hutchinson, W. Johnston, E. E. Jones, Kathleen Lawrence, Betty J. Poland, D. B. Stewart.

The Services

Capts. R. McIlwraith and J. A. Tulloch and Lieuts. S. W. Pleasants and D. Train, R.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in North-West Europe.

Major (Temp.) P. C. Mitchell, R.A.M.C., has been awarded the M.C. in recognition of gallant and distinguished services in Italy.

The President of the U.S.A. has awarded the Soldier's Medal to Capt. J. McLean, R.A.M.C., in recognition of distinguished services in the cause of the Allies.

The Order of the Star of Nepal, Fourth Class, has been conferred upon Capt. Barnett Freedman, R.A.M.C. (since died), by His Highness the Maharaja in recognition of distinguished services in the cause of the Allies.

The Efficiency Decoration has been conferred upon the following officers of the Territorial Army: Lieut.-Col. (Temp. Col.) A. O. Bekenn, O.B.E., R.A.M.C., T.A.R.O.; Majors (Temp. Lieut.-Cols.) G. A. Kane, C. F. Mayne, O.B.E., J. E. Morrison, and W. Morrison, M.C.; Majors L. J. Beynon, E. S. Kirkhouse, and G. B. Matthews; and Capt. N. W. Kidston, R.A.M.C.

The following appointments have been announced in recognition of meritorious services:

O.B.E. (Military Division).—Lieut.-Cols. (Temp. Cols.) J. Rannie, T.D., and S. J. L. Lindeman, M.C., R.A.M.C.

M.B.E. (Military Division).—Major (Temp. Lieut.-Col.) T. N. Hart, and Capt. (Temp. Major) J. W. Campbell, R.A.M.C., T.A.; Capt. Marguerite E. M. Day, R.A.M.C.

Freed by U.S. Forces.—Capt. A. Farquhar, R.A.M.C.

Repatriated.—Major D. L. Charters, R.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Killed in action.—Lieut. Frederick William Marshall Greaves, R.A.M.C.

Accidentally killed in India.—Capt. Christine Mary Edmonds, R.A.M.C.

NAVAL MEDICAL COMPASSIONATE FUND

A meeting of the subscribers to the Naval Medical Compassionate Fund will be held at the Medical Department of the Navy, 64, St. James's Street, S.W.1, on Friday, April 27, at 3 p.m., to elect six directors of the fund.

Medical Notes in Parliament

National Health Service

On April 12 Dr. Summerskill asked what purpose had been achieved by issuing the White Paper on the health services in view of the fact that Mr. Willink, in response to representations from the B.M.A., proposed an alternative structure fundamentally different from that outlined in the White Paper. She further asked why the proposed salaried medical service operated from health centres and offering a new advance in medical practice had been dropped at the request of the B.M.A. Dr. Summerskill also asked what was the purpose of the experimental health centres contemplated in the alternative proposals to those contained in the White Paper, in view of the fact that they would provide accommodation from which doctors could conduct private practice more conveniently but on the same terms and lines as those practising from their homes. Mr. Willink answered these three questions together. He said he welcomed the opportunity to clear up misunderstanding on the matter. The proposals in the White Paper were for discussion before the Government decided on the terms of draft legislation. Discussion was invited with all the major professional and other organizations affected, and this had been and was still taking place. In the course of it various possible modifications of the detailed proposals had been discussed by Mr. Johnston and himself. Soon Mr. Johnston and he would consider with their colleagues some of these alternative methods of achieving the White Paper's objective, which was a comprehensive service of health for the nation. The Government would have then to decide whether these or any of them were desirable alternatives. Before informing the Government of their views on these possible alternatives, the various organizations—medical, dental, voluntary hospital, local authority—were considering, on reports from their representatives who took part in the talks, the matters which had been discussed. To some of those reports or to varying rumours about those reports recent references had been made. When the views of the different organizations were available the Government would decide upon the content of draft legislation for submission to the House. Discussion of much detail which might not need to be included in the Bill itself would go on. Until then the three stages of the procedure originally laid down—the White Paper, discussion of the White Paper, and final preparation of draft legislation—were being adhered to. The objects of this second stage had been those which were clearly set out in the introductory paragraphs of the White Paper.

Dr. Summerskill suggested that the B.M.A. and other medical organizations had already thrashed out every question of principle with the Ministry. Did not the report, which had been published and was in the hands of every doctor and of many lay people, alter every principle laid down in the White Paper? Mr. Willink said Dr. Summerskill was under a complete misapprehension. The White Paper afforded a new focus for discussion, particularly after it had been discussed in the House of Commons. No report had been published. Every copy was marked "Not for publication." Dr. Summerskill was wrong when she spoke of anything having been dropped. The Government as a whole had not considered the outcome of these negotiations.

Dr. Russell Thomas suggested that Mr. Willink had changed his mind on realizing that Parliament had no mandate to enslave a free profession. Mr. McNeil asked whether the Government had indicated to the B.M.A. that the proposals they were now discussing were acceptable to the Government as a basis for negotiation. Mr. Willink repeated that Mr. Johnston and he had not discussed with their colleagues the outcome of these negotiations. His statement did not mean that he himself was dissatisfied with the conclusions reached by Mr. Ernest Brown.

Mr. Pethick Lawrence asked if Mr. Willink had given any indication to the medical authorities that he himself would support these proposals with his colleagues in the Government. Mr. Willink said that in discussions of this kind he would not express an attitude to any proposals which might embarrass the Government's ultimate decision on them.

Mr. Shinwell said members of the B.M.A. had stated that their interpretation of their discussions with the Minister led them to conclude that he had made certain concessions, or had agreed to put modifications before his colleagues in the Government. Mr. Willink said he had no knowledge of what statements had been made by members of this large Association.

Dr. Summerskill gave notice that she would raise the subject on the adjournment at the first opportunity. Later Mr. Greenwood asked the Government to arrange for a White Paper to be issued showing the departures made from the White Paper which had been discussed and approved by the House. He also asked for a free and open discussion on the matter before the B.M.A. conference at the beginning of May. Mr. McEntee asked why a paper marked "Not for publication," and not made available to the House, had been sent out by the B.M.A.

Mr. Eden said this last question was not within his jurisdiction. As regards Mr. Greenwood's question, no conclusions whatever had been reached as the result of the conversations since the House debated the White Paper. If conclusions were reached, they would have to be considered by the Cabinet and after that a report made to the House. At this stage they were purely exploratory, and members of the Cabinet were entirely unaware of them. Mr. Greenwood, while accepting these assurances, said tentative conclusions had leaked out all over the country and in every hospital. He still thought a White Paper should be issued to the House. Mr. Eden said no abnormal procedure had been followed. Conversations had been going on not merely with the B.M.A. but with local authorities as well. The first stage was that the Government must be made aware of the situation and must come to its decisions. It would then consider how most fairly to present its conclusions to the House so that the House might have a fair and full opportunity to express itself.

Pure Milk

Lord Bledisloe in the House of Lords on April 11 asked what the Government was doing to augment the pure milk output; whether they agreed that mastitis, contagious abortion, sterility, and Johne's disease involved a yearly underproduction of 200,000,000 gallons of milk, and whether remedial measures capable of immediate application were contemplated. He said he was pleased that for the first time the representatives of the Ministry of Agriculture and of the Ministry of Health would both speak in an agricultural debate. He was also glad that Lord Moran, President of the Royal College of Physicians, would take part. Lord Bledisloe asserted that in quality of milk supply, individual consumption of milk, yield per cow, bovine disease, veterinary treatment, and the numbers and qualifications of veterinary surgeons, Great Britain compared unfavourably with most other civilized countries. The problem needed to be tackled at its source, which was animal disease. Nearly half the cattle in the country were affected with tuberculosis and reacted to the tuberculin test, although only 0.5% of the cows gave milk containing bovine tuberculosis germs. It would be serious if all cattle reacting to the tuberculin test were slaughtered, as in the United States. All the diseases he had named were, in the opinion of veterinary surgeons, preventable.

There were approximately 3,000,000 dairy cattle in Great Britain with an average annual yield of 500 gallons. The pre-war human consumption of milk per head was 0.45 of a pint daily. It was now 0.58 of a pint, an increase of 30%. The well-to-do had consumed less, the very poor had consumed more, and the balance of the increase had been due to the National Milk Scheme. He suggested that the lowest target to aim at was 0.75 of a pint daily with rather more for children and nursing mothers. On that basis the national consumption would be over 2,000,000,000 gallons per annum, the product of over 1,000,000 additional cows. At present the yield per cow was lower owing to lack of feeding concentrates.

Disease in Cattle

The human consumption of milk and the bovine milk yield in Great Britain were low by comparison with other countries. The Survey Committee of the National Veterinary Medical Association had declared in 1940 that the "wastage of milk caused by disease among dairy cattle was colossal." The Committee on Cattle Disease of the Economic Advisory Council had asserted in 1934 that the milking life of a dairy cow was only half what might be expected under ideal conditions. That committee said that 58% of the cows passing out of herds were disposed of on account of disease. The incidence of bovine tuberculosis over the country varied, but was put at about 40%. In some areas the percentage was nearer 90. The loss to the farmers from this disease was put at £3,000,000 yearly. The right method of controlling this disease was on an area basis, gradually extending the areas of immunity.

Relatively little had been done by the Government to eradicate bovine tuberculosis, and still less against the other four diseases he had specified in his opening question. Losses from these were more serious. All four diseases were increasing, and the annual loss of milk through them was put at about 200,000,000 gallons. As a policy for the Government he suggested a survey of the incidence of disease throughout the country; an increased bonus for milk from attested herds; and an intimation that within five or ten years milk from herds not clear of tuberculosis and other preventable disease would not be accepted for human consumption. He further suggested a free State veterinary service; the marking of cows eliminated from attested herds so that they could not be sold into other herds; compulsory vaccination of calves against contagious abortion; compulsory health service for cattle instead of the present voluntary panel scheme; establishment of disease-free areas and their extension; establishment of a State abattoir service.

Lord Cranworth said the veterinary profession had introduced two vaccines which were approximately 90% effective against contagious abortion. The use of one was compulsory in the Province of Quebec. Lord Iveagh spoke on mastitis and said the hands of his milkers continued to be infected, however well they cleaned them. The infection was due to the handles of the churns which came back from creameries where they had been handled by men who did not clean their hands after handling dirty churns from other places. Workers in cowsheds who had infected hands could infect every door-handle, every milking stool. This disease had never been found on the hands of those who did not handle milk or milk churns. It did not readily multiply on the human hand.

Scheme of Control

The Duke of Norfolk could not accept as accurate all the figures which had been given. Milk delivered off the farms during the last six months was 12% more than for the corresponding six months of 1939-40. There had been some adverse effect on the cleanliness of the milk, but all possible steps had been taken to maintain cleanliness and purity. There were now 635,000 attested cattle. The four major diseases mentioned by Lord Bledisloe were not notifiable. He could not admit that they were entirely avoidable. Research was at present handicapped by shortage of labour, buildings, and veterinary surgeons. A voluntary scheme for control of diseases of dairy cattle had come into operation in England in June, 1942, and in Scotland a few months later. The Ministry of Agriculture provided free laboratory diagnosis, free abortion vaccine, and, at a low price, sulphanilamide for certain forms of mastitis. Vaccination of calves against contagious abortion was introduced at the end of 1944. Unfortunately the Ministry of Agriculture had been unable to supply the whole of the vaccine demanded and had to curtail the scheme. Farmers had been encouraged to dispose of animals suffering from disease not readily susceptible to treatment. Orders for slaughter were resorted to only in very bad cases. Proposals on the training of veterinary surgeons would come before the Council of the Royal College of Surgeons that week and should carry matters further towards legislation to give effect to the Loveday report.

Medical Opinion

Lord Addison said clean milk could not be expected until the water supplies of farms were boldly improved. Lord Moran said that if consumption of milk were increased to 0.8 of a pint per head daily the nation would need a 75% increase in winter production and a 30% in summer production. Dairy cows would have to be increased from 3,200,000 to 4,500,000. That was not an unreasonable target. The National Milk Scheme should become permanent after the war. Milk must eventually be sold by its nutritive value, not by its volume. The controversy on pasteurization was moribund. The bacteriologist had laid it down that this treatment did not affect the nutritive quality of milk. It was not easy to understand why microbes in water caused dismay to the public while microbes in milk were accepted with equanimity. If cattle diseases could be got rid of, milk production would go up by 25%.

Lord Geddes urged research to discover how cows' resistance to disease was affected by varying types of food and by the mineral content of the soil. Lord Glentanar said farmers declared that it was always the best milking cows which developed mastitis. Over-production of milk put a great strain on the metabolic process. Lord Teviot said milk should make contact with the air as little as possible. An eminent physician told him that milk-bars were places which spread diseases.

The Earl of Listowel recalled that under the Food and Drugs Act, 1944, administrative responsibility for hygienic milk production on farms would pass from local health authorities to the Ministry of Agriculture. This change could not be implemented by the Ministry without an increase of its staff, impracticable till after the war in the Far East. Available statistics did not expose the whole extent to which public health had been undermined by dangerous milk. In 1942 a warning had been sounded by a committee of the Medical Research Council on Tuberculosis in Wartime. The death rate did not indicate the ravages of non-pulmonary tuberculosis. They did not know the full extent of the diseases of human, not bovine, origin carried into homes by germs from those who had handled the milk. The plain fact was that our dairy cattle were riddled with disease and appalling damage had been done to thousands of people, mainly in the rising generation. The most effective prophylactic method at present was that which attacked the disease-carrying germ not in the animal but in the product. The quantity of milk heat-treated would be increased by the payment of an allowance from the Ministry of Food for milk so treated. Surveys had been completed in 216 of 621 areas in England and Wales on the classes of milk supplied in each area and the availability of apparatus for heat treatment. The Ministry of Health was convinced that heat treatment, properly carried out, destroyed the germs which materially affected the nutritive quality of the milk.

On the following day, April 12, Lord Listowel amended his remark that the dairy cattle of Britain were riddled with disease.

Health of African Troops

In the House of Lords on April 10 the Duke of Devonshire made a statement on his visit to the West and East African troops serving in India and Burma. He said that the morale of the troops was very high and their health very good. The doctors had been rather afraid that the relative immunity which Africans had obtained from all types of malaria prevalent in their own countries might be of no avail against the somewhat different types prevalent in Burma, but, on the whole, those fears had proved to be ill founded, and the incidence of malaria, when one compared the present campaigns with those of the past, had been remarkably low. The food had been very good indeed, and that had certainly helped to keep the African troops fit and cheerful. He had visited a number of hospitals and was told that there had been no shortage of drugs or medical requirements, which were in sufficient supply.

No. 13

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended March 31.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each Infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Rate per 1,000 total births (including stillborn)			38					31		

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* there was a lowered incidence of infectious diseases, the total notifications for the country falling by the following amounts: measles 3,324, whooping-cough 330, scarlet fever 161, dysentery 26, diphtheria 4.

In Cheshire, Knutsford U.D., 16 cases of dysentery were notified. Warwickshire reported 32 fewer cases of whooping-cough than last week. Measles notifications fell by the following numbers: Yorks West Riding 664, Middlesex 529, Gloucestershire 273, Devonshire 182, Surrey 171, Somerset 157, Lancashire 156. Small increases were recorded in London, Essex, and Hertfordshire.

Dysentery still remains prevalent. Fresh outbreaks occurred during the week in Wiltshire 31 (Salisbury M.B. 24), Staffordshire 13, and Yorks East Riding 11. The other large returns were Lancashire 59, London 39, Gloucestershire 29, Surrey 22, Middlesex 21, Yorks West Riding 21, Warwickshire 17, Suffolk 12, Derbyshire 12, Somerset 10.

In *Scotland* also infectious diseases were less prevalent, the returns being lower by the following numbers: measles 140, whooping-cough 73, acute primary pneumonia 56, dysentery 41, scarlet fever 35. The incidence of dysentery is still very high, although it has fallen by one-third during the past fortnight; the largest returns were Edinburgh 50, Glasgow 21, Dundee B. 15, Fife County 13.

In *Eire* whooping-cough notifications were 20 fewer than last week, and measles 13 fewer, while those for scarlet fever rose by 10, and for diphtheria by 1. Diphtheria continues to be widespread; the 97 cases occurred in fifty-two areas.

In *Northern Ireland* notifications of scarlet fever went up by 14, whooping-cough by 12, and diphtheria by 4; those for measles dropped by 4.

Diphtheria

There is usually a rise in the incidence of diphtheria in the first weeks of the year. Not only has this *not* happened this year but the number of notifications during the first twelve weeks of 1945 was smaller than that reported during the twelve weeks of last summer, when diphtheria was at the lowest level ever recorded. The notifications during the first twelve weeks of the year during the period 1940–5 number: 8,536, 13,525, 10,822, 10,099, 8,279, 5,498. An interesting feature of the recent returns is that the rises in the total for the whole country are often due to local outbreaks. Increases of from 10 to 65 during the past three months have been recorded five times in Lancashire, four times in Yorkshire, twice in Cheshire, and once in Durham, Warwickshire, and Wales. The most notable of these local outbreaks were those in Caernarvonshire, Bangor M.B., where the cases rose from 4 to 55 during Jan. 13–20, and in Yorks North Riding, Whitby R.D., where the rise was from 0 to 24 during March 10–17. Perhaps these severe local outbreaks occur in pockets of non-immunized children. The decline in the incidence of diphtheria has not been uniform throughout the country, and the north has now a larger percentage of the cases than a few years ago. The percentage distribution for the first twelve weeks of the past six years is:

Region	1940	1941	1942	1943	1944	1945
London	4·4	4·4	3·7	5·0	4·7	4·1
South-East	6·0	4·1	3·5	3·7	3·7	4·1
South-West	5·5	7·7	3·5	2·7	2·9	3·8
South Midland ..	5·1	6·8	4·1	2·6	3·2	2·9
Eastern	3·1	2·2	2·1	2·4	3·1	3·0
West Midland ..	12·9	13·8	12·1	15·6	15·5	13·3
North Midland ..	6·4	8·2	6·8	5·6	3·9	5·0
North-West	20·2	22·8	26·5	25·9	22·3	23·0
Yorkshire	11·4	11·6	15·3	16·9	15·7	15·4
Northern	9·2	6·8	12·2	11·1	14·8	15·7
Wales	15·8	11·5	10·0	8·4	10·0	9·5
Port Sanitary Districts	0·1	0·2	0·2	0·04	0·1	0·2
England and Wales ..	100	100	100	100	100	100

The fatality rate, judged from the experience of the great towns, has also fallen, and is only half of the rate of five years ago. For the 126 great towns the deaths per 1,000 cases during the first twelve weeks of the year during 1941–5 were 62, 51, 48, 34, 30. It is not possible from official statistics to compare the age distribution of diphtheria cases prior to June, 1944, but the reports of medical officers of health suggest that the age of attack has increased and adolescents and adults form a larger proportion of the cases than ten years ago. Despite the lowered killing power, the present form of diphtheria is of a virulent type and often leads to a grave type of paralysis.

The success so far obtained in depressing the incidence of diphtheria does not warrant any let-up in the immunization campaign. The majority of children have now been protected, but the proportion does not approach 75%. A few years' births can easily reverse the proportion of immunized to non-immunized if there is any falling off in the numbers of young children being inoculated.

Week Ending April 7

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,343, whooping-cough 1,043, diphtheria 453, measles 22,599, acute pneumonia 693, cerebrospinal fever 66, dysentery 306, paratyphoid 3, typhoid 5. One case of typhus occurred in Liverpool port health district during the week ending March 24.

Medical News

Sir John Boyd Orr, M.D., F.R.S., standing as an Independent candidate in the Scottish Universities Parliamentary by-election, has been returned with a majority of 12,020 votes over the Liberal National candidate. Dr. Robert D. M'Intyre, standing as a Scottish Nationalist, has been returned for the Motherwell Division with a majority of 617 over the Socialist candidate. Dr. M'Intyre is at present in the service of the Glasgow Corporation Public Health Department.

Dr. W. B. J. Pemberton, of Bermondsey, S.E., has been adopted as Liberal National candidate for the Parliamentary Division of West Bermondsey, and Dr. D. Stark Murray as Labour candidate for Richmond, Surrey.

The following films will be shown by the Scientific Film Association at the Royal Society of Medicine, 1, Wimpole Street, W., on Wednesday next, April 25, at 5.30 p.m. and again at 8 p.m.: "A Cautionary Tale about Sepsis," "A B C D of Health," "The Treatment of Bronchiectasis in Childhood," and "The New Lot." Admission will be by ticket only, and those who have not already done so should apply immediately to the honorary secretary of the Medical Committee, Dr. S. J. Reynolds, 14, Hopton Road, S.W.16.

The Association for Scientific Photography has formed a Medical Group which is holding its first meeting on Wednesday, April 25, at 6 p.m. in the Hastings Hall, B.M.A. House, Tavistock Square, W.C. Business will include passing rules and electing two Provincial members to the committee. Fl. Lieut. H. Mandiwall, M.B., will then read a paper on "Visual Education in Medicine." Each member may introduce two visitors at this meeting.

Prof. P. A. Buxton, F.R.S., will give an address on "Natural History of Scrub Typhus" before the Royal Institution (21, Albemarle Street, W.) on Friday, April 27, at 5 p.m.

Tuesday, May 1, is Hospitals Day for London. Those who wish to help should write to the appeal secretary of their local voluntary hospital or to Lord Luke, Chairman, Hospitals Day, 36, Kingsway, W.C.2.

Sir Howard Florey, F.R.S., professor of pathology in the University of Oxford, has left London for Sweden to lecture on subjects connected with penicillin. His visit has been arranged by the British Council at the invitation of the Swedish Medical Society. Lectures to medical organizations in Stockholm and other cities on "The Experimental Background to the Clinical Use of Penicillin" and "The Use of Penicillin in the Clinic" will be illustrated by films and slides, and Sir Howard has with him a film on penicillin laboratory investigations to show to specialists. He will also visit Finland.

Two scholarships of £50 each are to be awarded by the National Association for the Prevention of Tuberculosis to health visitors wishing to specialize in tuberculosis work. Details from the Secretary-General, N.A.P.T., Tavistock House North, Tavistock Square, W.C.1.

The President of the Polish Republic has conferred the Order of Polonia Restituta, Second Class, on Sir John Fraser, Bt., K.C.V.O., Ch.M., F.R.C.S.Ed., principal and vice-chancellor of the University of Edinburgh, and the Third Class of the Order on Prof. L. S. P. Davidson, M.D., F.R.C.P., professor of medicine, University of Edinburgh.

Summer courses for leaders of physical recreation, arranged by the Central Council of Physical Recreation, will be held at Lowther College, Bodelwyddan Castle, Abergele, from July 28 to Aug. 25. Thirteen different courses will fill the four weeks, and are open to men or women of 18 and over, and there is also one course for boys and girls of 16 and over who wish to help with physical recreation in clubs, youth centres, etc. Full particulars of fees and accommodation can be obtained from the General Secretary, Central Council of Physical Recreation, 58, Victoria Street, S.W.1.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Acute Gastro-enteritis

Q.—*I have been attending many cases of "abdominal influenza," with severe and continuous pain in the upper abdomen, slight vomiting, but no bowel action. The pain persists for 10 days, gradually lessening. Sometimes there was a less severe repetition. The temperature is about 100–102° F. (1) What is the pathology of this complaint? (2) How can such an attack be distinguished in the early stage from an "acute abdomen" needing operative surgery? (3) What is the treatment?*

A.—We may take leave to doubt whether such a condition as "abdominal influenza" actually exists. Certainly there seems to be no evidence that influenza virus or antibodies have been demonstrated in cases so classified. Most illnesses of this kind are Salmonella infections, acquired from water, food, or carriers. Diarrhoea may not occur, and it is usually absent in paratyphoid fever. Relapses or second attacks are not infrequent. The underlying morbid anatomy is an acute gastro-enteritis. An aetiological diagnosis can be made by blood culture, agglutination reactions, or cultures from the stools. Differentiation from surgical lesions is made by the early presence of fever, the absence of rigidity or severe tenderness, and the general march of the symptoms. There is no specific treatment, as neither penicillin nor sulphonamides are effective. A less common cause of symptoms of this type is a sub-icteric attack of infective hepatitis.

Acute Lumbago

Q.—*What is the pathology of acute lumbago—the instantaneous onset of agonizing, immobilizing pain often unassociated with muscular effort at the time? If it is due to spasm of the erector spinae muscles, then what is the cause of the spasm and what maintains it?*

A.—To discuss the pathology of acute lumbago fully would take pages. The cause of the instantaneous onset of severe pain which is occasionally met with is generally believed to be muscle spasm affecting small areas of the erector spinae or quadratus lumborum. Vigorous effort is quite unnecessary to give rise to it; even a small movement in changing posture may suffice, especially if the spine is in a twisted position or if there is any morbid condition of the facets of the intervertebral joints, inflammatory or degenerative, or thinning of the intervertebral disks with or without prolapse of the nucleus pulposus, so that the vertebrae are not held firmly by the attached ligaments. The acute pain which is set up in the knee when a loose body or a thickened synovial fringe is caught between the articular surfaces is of the same nature. Another cause is believed to be herniation of fat lobules through small apertures in the layers of deep fascia which have been demonstrated by biopsy. Local areas of inflammation which may be due to gouty deposits may be irritated by slight movement and an acute spasm results in adjacent muscle bundles. The relief obtained by injecting 10 or 20 c.cm. of 1% novocain saline is due to relaxation of the spasm; suitable manipulation may produce the same result. Fuller discussion of these factors will be found in papers by Capener (*Ann. rheum. Dis.*, 1944, **4**, 29) and by Ackerman and Copeman (*Quart. J. Med.*, 1944, n.s., **13**, 37).

Ill Effects of Tobacco

Q.—*What is the active principle in tobacco which is responsible for the well-recognized effects of tobacco poisoning on the gastro-intestinal mucosa, the heart, and the eye? Is there any method of assaying the blood or tissue levels of this substance?*

A.—It is uncertain what the question means when it speaks of the well-recognized effects of tobacco poisoning on the gastro-intestinal mucosa, etc. While some clinicians believe that smoking increases the tendency to gastric ulcer, others deny this, and the work of Schnedorf and Ivy (*J. Amer. med. Ass.*, 1939, **112**, 898) failed to discover any effect of smoking on gastric acidity. Since Ivy is an experienced and impartial worker, great weight must be given to his results. Nor can it be said that the effects of tobacco poisoning on the heart are well recognized. It is, of course, true that athletes in training do not smoke, but the detrimental effect may not be on the heart. While some observers think that smoking increases the tendency to coronary disease, there is no actual evidence that it does. So far as the eye is concerned, tobacco amblyopia is certainly a well-recognized effect. It has always been presumed to be due to the nicotine present in tobacco smoke, but there is no proof of this.

Morquio's Disease

Q.—*A child aged 3 years, suspected of rickets on account of some deformity of the chest and spine, has been x-rayed, and diagnosed as probably a case of Morquio's disease. What is the treatment for this unusual condition?*

A.—This "disease" was also described by Brailsford in 1926. It is one of the queer congenital dysplasias, causing dwarfism and multiple deformities of the spine and limbs. A synonym, equally illuminating, is "chondro-osteodystrophy." Although affecting mainly the bony and cartilaginous tissues, there is no known disturbance of calcium metabolism. The origin of the condition would appear to be a developmental anomaly arising in intra-uterine life. For the "disease" there is no treatment, but for the deformities orthopaedic correction may be indicated.

The Pain of Abortion

Q.—*In a case where there was a miscarriage in a primigravida at 20 weeks, and in another where large quantities of progesterone had been given to prevent a threatened abortion, when the abortions became inevitable there was an extreme amount of pain, consisting of long spasmodic contractions much longer in time and stronger in severity than would be expected. Could the progesterone be responsible and have there been any similar experiences?*

A.—The amount of pain experienced during abortion is very variable—as it is during labour at term. The pain caused by contractions of the uterus, as distinct from that due to distension of the vagina and perineum, is not dependent on the duration of the pregnancy and the size of the baby, and it is not uncommon for abortion pain to be extremely severe and distressing to the patient. Some women who have experienced both, assert that the pain of abortion is worse than the pain of labour. As suggested in the question, this may sometimes be explained by the fact that the premature expulsive contractions of the uterus are spasmodic or colicky and incoordinate. The outlook of the woman may be important; unlike labour at term, abortion is accompanied by a sense of disappointment and the knowledge that the discomfort will be fruitless. This can not only affect the woman's resistance to pain but in itself disturb uterine polarity. Although it has been suggested that progesterone renders uterine contractions incoordinate in the sense that it prevents purposeful expulsive action, and although spasmodic dysmenorrhoea rarely occurs except when the uterus has been subjected to the influence of this hormone, there is no evidence as yet to show that abortion is more painful when it follows progesterone therapy. It can certainly be very distressing even when progesterone has not been administered—as in the first case mentioned in the question.

Treatment of Cholecystitis

Q.—*Have any of the sulphonamides been used in the treatment of chronic cholecystitis, and if so with what results—or is surgical procedure still essential? A patient on x-ray examination shows no stones but a low-grade cholecystitis. Gastric symptoms are almost absent but there is some general rheumatism.*

A.—The sulphonamide drugs are secreted in the bile in the same concentrations as, or higher than, they occur in the blood. It is therefore easily possible to secure bacteriostatic concentrations of these drugs in the gall-bladder. No record of the effects of treatment of chronic cholecystitis in this way has been noted. It would presumably be necessary to give the drug for a considerable period of time in a dosage of the order of 1 gramme 6-hourly, and a careful watch would have to be kept on the white blood count, particularly during the second to sixth weeks of treatment. From the scientific point of view there would be little to recommend trying such a treatment in a single case; but in the present instance, where the indications for surgery seem rather slender, it might be a justifiable clinical experiment.

Nutritive Value of Egg-white

Q.—*Albumin water is sometimes advised for ill patients. What is the nutritive value of egg-white?*

A.—The caloric value of an egg weighing 50 grammes is 68. The yolk of the egg provides 53.5, and the white 14.5 calories, which is derived from 3.5 grammes of protein. The white is made up with either 6 or 10 oz. of water, and a 2-oz. feed will contain about 3 or 5 calories. This is a very small amount, and a lump of sugar weighing 5 grammes provides 20.5 calories. In three books on paediatrics albumin water is still mentioned among other fluids in the treatment of gastro-enteritis, and two of the books give directions for making it; one says it should not be used as it may cause vomiting if the child is sensitive to eggs; three other books do not mention its use. It seems a wasteful and expensive way of giving a very little food.

Injury from Ear-syringing

Q.—*Does syringing of ears (1) cause rupture of ear-drum, or (2) precipitate an acute suppurative otitis media in an appreciable number of cases where an ordinary metal syringe is used? A man with Eustachian catarrh developed acute suppurative otitis media (right) after syringing of the ear.*

A.—(1) If done properly syringing should not cause rupture of the ear-drum. The stream of water should always be directed against the posterior meatal wall. Most alleged cases of rupture are in fact infections caused by syringing in the presence of an unsuspected pre-existing dry perforation. Rarely the nozzle of the syringe becomes detached and a genuine traumatic perforation results.

(2) The same considerations apply. Infection cannot take place through an imperforate drum. It may well appear to do so, as suppuration follows the acute catarrhal condition where the organism is sufficiently virulent or the patient's resistance is lowered.

Rotation of Hip-joint

Q.—*How does the orthopaedist define internal rotation of the hip-joint? Presumably the right femur with hip and knee extended would be internally rotated by clockwise rotation. If hip and knee are now flexed and the foot carried over to the left side of the body is this internal rotation of the hip, though the femur now rotates contra-clockwise?*

A.—There is no ambiguity about rotatory movements at the hip, provided that comparisons with the hands of a clock are avoided. The axis of rotation is the centre of the femoral head, and since its surface forms the greater part of an almost perfect sphere, rotation can be estimated with equal facility whether the hip is flexed, abducted, or adducted. Internal rotation is a rotation towards the mid-line of the anterior sector of the thigh; the anterior surface of the femoral head moves medially and more deeply into the acetabulum; the great trochanter moves forwards and, if it lay in the neutral position, becomes slightly more prominent; and the lesser trochanter moves posteriorly and laterally, so that it often becomes invisible in an antero-posterior radiograph.

A simple method for estimating the range of internal rotation, though not accurate, is good enough for almost all clinical work. The patient lies supine with his feet together, the great toes pointing to the ceiling. Move the sound lower limb out of the way by abducting it; then with the ankle on the affected side in the neutral (standing) position, rotate the whole lower limb inwards, taking care not to shift the pelvis out of the horizontal plane. Rotation inwards through one-third of a right angle would be recorded as I.R. 0-30°. It may be that the limb shows some internal rotation deformity—i.e., the foot cannot be brought into the vertical plane when the patient is supine—then one starts from the position of deformity and measures the rotatory movement that is possible: it might be, say, 10-35°. In such a case there would, obviously, be no range of external rotation. A prettier method is to place the patient supine with the knees flexed at a right angle over the edge of the bed. The leg can then be used as the arm of a protractor, and it is certainly easier by this method to assess the range of rotation accurately. The source of error in both methods is the possible ligamentous instability of the knees: there is a small range of rotation even in the normal joint.

Immunization against Non-endemic Diseases

Q.—*If there is a risk of the introduction of typhoid, cholera, and typhus into this country from the Continent after the war, should immunization against these infections be encouraged?*

A.—Outbreaks of typhoid, cholera, and typhus in different parts of Europe and the Far East are hazards which will require careful and prompt handling if they are not to spread to other centres, including our own country. Typhoid and cholera could be imported here by people who have suffered typical or atypical attacks of these infections and are still carriers of the organism. Typhoid, however, is nowadays a rare infection among the troops on account of prophylactic vaccination, and as they are the principal migrants it seems unlikely that there will be many fresh introductions of this disease during and after the war.

Cholera is not now endemic in Europe; but it is in Burma, India, and farther East. There is no general prophylactic vaccination against cholera, so that convalescent carriers returning from these countries are to be expected. However, cholera is predominantly a water-borne infection, and unless there were a breakdown in sanitation it would have little opportunity to spread in this country. Anticholera vaccines are available, usually combined with T.A.B. vaccine.

Typhus is a louse-borne disease, and if outbreaks in Europe and elsewhere can be dealt with as effectively as was the Naples epidemic by the widespread use of the delousing powder D.D.T., there seems little risk of its being imported. Typhus vaccination is used extensively in the Services and no doubt would be available, if needed, for civilian use. Vaccination against these infections is generally reckoned to give protection for at least two years; after that time, if there is likely to be exposure to the risk of infection, a repeat "boosting" dose is given.

Measles Prophylaxis

Q.—*What are the current views on the prophylaxis of measles—i.e., by the injection of convalescent serum, immune globulin, etc.?*

A.—When a case of measles has occurred in a family there is a choice of two alternatives: (1) to aim at complete protection of the susceptible contacts, who will, of course, become susceptible again between two and three weeks later; or (2) to attenuate the infection, which lets the child off with a mild attack and gives it, so far as we know, lasting immunity. Measles is rare in infants under 3 months of age, but from 3 months to 2 years children should, if possible, be completely protected, and for this purpose an intramuscular injection of 5 c.cm. of pooled convalescent measles serum within 5 to 6 days of exposure—i.e., 1 to 2 days after the appearance of the rash in the original case—is the most reliable procedure. However, convalescent measles serum is not easily obtainable, and the doctor then has a choice of pooled adult serum, obtainable in many areas through the M.O.H. and the E.P.H.L.S., parental whole blood or serum, or placental globulin, obtainable commercially. The protecting dosage of adult serum for children under 3 years of age is 10 c.cm. (double that amount of whole blood), and of placental globulin 5–7 c.cm. For attenuation, half the dose required for protection is used; a good working rule is to give 1 c.cm. of adult serum for every year of life after 2 years. Doctors must remember that there is a small risk of "homologous serum" jaundice from 2 to 4 months after the injection, particularly if pooled serum is used. Lately a new product, gamma globulin, has been used in America and may soon be available here. It is a concentrate of the natural antibodies in adult serum, and controlled trials indicate that its potency is about twice that of convalescent serum.

Miscarriage and Rh Factor

Q.—*In a recent miscarriage (primigravida) at 20 weeks resulting in a live birth—apparently normal foetus which lived for 15 minutes—the mother was of blood group O and Rh-negative; (foetus was blood group B and Rh-positive. W.R. was negative. Could this be sufficient to cause the miscarriage? and is there any advice that should be given to the mother in respect of any future pregnancy?*

A.—From the information given it is unlikely that the blood-group differences between mother and child were responsible for the miscarriage at 20 weeks, unless it was clearly a hydropic foetus. Rh incompatibility is only rarely the cause of such a disaster in a first pregnancy, unless the mother had become sensitized to the Rh factor by a previous blood transfusion. The mother's serum should be examined for anti-Rh agglutinins and for evidence of "incomplete" or "blocking" antibodies, and this should be done towards the end of any subsequent pregnancy. If evidence of anti-Rh is then forthcoming, steps should be taken to prepare to transfuse the infant immediately after birth with Rh-negative blood. Meanwhile the mother should be told not to worry about it, but to await further pregnancy hopefully.

John Knyveton's Diary

Q.—*Is it known whether Knyveton's "Diary of a Surgeon in the Year 1751–2," edited by Ernest Gray and published by D. Appleton-Century Company in 1938, is fact or fiction, or a skilful combination of both? It is a remarkable book if it is what it purports to be—and even more remarkable if it is not. There are, however, various anomalies, some chronological, which make one doubt its strict authenticity.*

A.—This question was dealt with by J. Paul de Castro in the journal called *Notes and Queries* (Feb. 1, 1941, **180**, 76). Mr. de Castro, the author of a life of Richard Mead, based his comments largely on Knyveton's activities during his leisure hours outside Infirmary Hall. Briefly, his criticisms are as follows: (*a*) With reference to the dinner at the Devil Tavern, it is pointed out that, as Knyveton himself says, Samuel Johnson was already a famous man, and it is therefore unlikely that two medical students would have been invited on the spur of the moment to join him at dinner in a very exclusive club. Further, Johnson is referred to as "the doctor." In point of fact he did not receive his doctorate until 1765. (*b*) The scenes described in the Rainbow Tavern are those of a "disorderly house"; yet only five years earlier this tavern was selected for the annual banquet of the Royal Society. (*c*) Knyveton and his friends took a walk "past the grounds of the new house of my Lord Mansfield." Sir William Murray did not become Lord Mansfield until 1755. (*d*) March 15, 1752, was not a fine and sunny day; on the contrary it was remarkable for the great damage caused by high winds.

There are a number of other criticisms, of which the following are samples. (*a*) Despite what Knyveton says regarding his preference for the anatomy book which had belonged to his uncle, there is surely something wrong here. The first edition of the *Anatomy* of Thomas Gibson was published in 1682, and Gibson died in 1722. The last recorded edition appears to have been the sixth (1703). Cheselden's book was very widely used in 1751. (*b*) Henry Baker, the author of *The Microscope Made Easy*, is said by the editor in the glossary to have been at one time President of the Royal Society. This is not the case. (*c*) Spallanzani was only 22 years old when the Diary was supposed to have been written; the first of his great papers did not appear until 1768. (*d*) Lind's *Diseases of Europeans in Hot Climates* is stated by Knyveton to have been "recently published." It was not in fact published until 1768.

It seems to be established that the book is not an authentic journal. There is no means of deciding whether it is pure fiction or a mixture of fact with fiction. Apart from discrepancies such as those noted, the facts are relatively accurate, and there is no doubt that the book does give a very clear and readable picture of the medical life of the time.

INCOME TAX

Car Allowance: Depreciation

"A." is employed whole-time in a number of hospitals. He receives an allowance of £*x* to cover repairs and road tax and a mileage allowance at the Civil Service rate. Can he claim depreciation?

⁂ The intention of the employing authority appears to be to bear the whole cost of the use of the car for professional purposes, and we are of opinion that the mileage allowance would be regarded as covering the depreciation of the car.

Investments in Building Societies: Start of Consulting Practice

C. C. M. inquires (*a*) whether there is any legal objection to investing more than £5,000 in various building societies, and (*b*) what is the position during the early years of the setting up of a consulting practice when expenses may exceed gross earnings.

⁂ (*a*) There is no such legal objection; if the £5,000 is exceeded the investor is nevertheless entitled to the benefit of any arrangement made by the building society under which the interest is paid without deduction of tax. (*b*) If the expenses exceed the gross earnings the resulting loss can be set off against other taxed income under Sec. 34 of the Income Tax Act, 1918. It is to be assumed, however, that the expenses claimed will be scrutinized from the point of view of the extent to which they can properly be allowed as incurred to obtain the small receipts expected in the very early years.

Liability of Married Persons

S. J. has married recently and inquires as to the effect on his income-tax liability.

⁂ As the marriage took place before April 5, 1945, the higher personal allowance (i.e., £140 in lieu of £80) will be due to S. J. for 1944–5. His wife will be entitled to the £80 personal allowance against her earnings up to the date of marriage, and to the married woman's earned income allowance of £80 against subsequent earnings in 1944–5. For 1945–6 the two incomes will in effect be aggregated and the tax assessed on the husband, but the wife will remain entitled to the £80 married woman's earned income allowance, but *not* to the reduced rate of tax—unless, of course, the £165 chargeable at the reduced rate on the husband's earnings is correspondingly restricted.

Cost of Instruments and Car

F. C. took up his first appointment last September, and has been told that he cannot claim a deduction for instruments for at least a year. He receives a travelling allowance of £100 a year and has been using a bicycle, but proposes to buy a car.

⁂ The cost of the initial equipment of instruments, etc., is regarded as an outlay of capital, and is not deductible for income-tax purposes. Repairs and replacements, however, can be charged against salary, provided that the maintenance of the equipment is wholly, exclusively, and necessarily required in performing the duties of the appointment. As regards the purchase of the car, the same rule applies. There is, however, the additional difficulty that as a bicycle has hitherto been sufficient F. C. will have to bear the onus of proving that a car has become necessary. If he can do this he is entitled to claim the excess of the running cost (including depreciation) incurred for professional purposes over the £100 a year allowance he receives.

LETTERS, NOTES, ETC.

Cause and Treatment of Stitch

Dr. J. KENNISH (London, S.W.4) writes: It may help Mr. Hollman (*Journal,* March 10, p. 355) and his friends if I suggest that one teaspoonful of confection of sulphur taken the night previous to the cross-country run will probably prevent the "stitch." About fifty years ago my fellow-student runners rarely had stitch after adopting the above treatment. We ran in all weathers—through rain, sleet, and snow. We always wore ordinary light running costumes.

Common Salt for Cleaning Teeth

Dr. H. WATSON TURNER (London) writes: In your "Any Questions?" (Feb. 17, p. 244) you give a most pleasing, simple, and excellent answer under the above heading. For 3½ years during this war I worked as temporary assistant dental surgeon to a county health service, and this question and answer opens up, to my mind, the most important fact of all our dental work—oral and nasal hygiene. School inspections are often far too casual—just a glance and note if the teeth are to be extracted or "filled." I always advise a saline solution as being simple, easily obtained, cheap, and effective as a mouth-wash and gargle for cleaning gums and cheeks, and brushing the teeth and washing the nose.

Relation between Herpes and Varicella

Squad. Ldr. H. R. E. WALLIS, R.A.F.V.R., writes: At the age of 12 I had chicken-pox. Last year, at 29, I developed herpes zoster and was confined to bed at home. Eighteen days after the onset of pain my daughter, aged 16 months, developed chicken-pox, and two days later my wife also succumbed. Neither of them had previously had chicken-pox or herpes. It seems, therefore, that chicken-pox does not confer an immunity against herpes. It would be interesting to know if the reverse is true. Perhaps the mechanism is that when a patient meets the virus he develops chicken-pox if he has not previously been infected and herpes if he has. Another point that may be relevant is that about 28 days before the onset of pain I had acute pain in the sacral region, which I considered at the time to be due to fibrositis caused by exposure to damp. Perhaps this was a prodromal manifestation at the time of entry of the virus into the nervous system. The last contact with a case of herpes zoster was nine weeks before my attack began, and I had not seen a case of chicken-pox for several months. Accounts of other experiences would be interesting. I am afraid I have no access to recent published work on the subject.

Dr. C. COLEY GRAYSON (Birmingham) writes: As another instance of the apparent connexion between herpes zoster and varicella may I cite the following: A girl 6 years old was brought to me on Feb. 26 with a typical herpes zoster of the upper abdominal wall on the right side. (Unusual at that age, I thought.) Her brother, aged 4, was brought to me to-day (March 13) with an unmistakable varicella. The interval between the two cases (15 days) is well within the incubation peiod of varicella. Both children had measles two months ago.

"General" Practice in Australia

A SURGEON with the British Pacific Fleet writes: One of the most impressive things to a medical visitor to Australia is the high standard of general practice. Most Australian graduates after completing their house appointments aspire to travel to England ("go home," as they say) and see some work there. A high percentage achieve their ambition and not only go home, but while there obtain higher qualifications such as the M.R.C.P. and F.R.C.S., with the result that a relatively large proportion of Australian practitioners possess these qualifications. Quite apart from this, however, a sound curriculum and good teaching in the Australian Universities have combined with the natural enterprise found in a young country and fostered by its vast spaces and scattered population to produce a very competent type of all-round country practitioner with much initiative, as the following incident will show. A practitioner "out back" had under his care a boy aged 13 with osteomyelitis of the upper end of the tibia. He operated and drained a subperiosteal abscess, and for a time the boy appeared to be doing well, as the local condition subsided and healing took place. His general condition, however, began to deteriorate; he became cyanosed and dyspnoeic, and developed precordial pain with a fast, weak pulse. The practitioner diagnosed suppurative pericarditis. There was no consultant available from whom to obtain help, and he related quite simply how the only person with whom he could discuss the case was the boy's own father, who agreed that his son was dying and consented to an operation. The practitioner explained the desperate nature of this; he had not only never done the operation but had never seen it done. As the boy was too ill for a general anaesthetic, a little novocain was infiltrated into the presternal tissues as he lay in bed. This intrepid practitioner then very modestly and simply explained that he had been afraid of haemorrhage from the internal mammary artery. So he drilled a hole through the sternum with a perforator and burr. The pericardium bulged into this opening and he incised it, evacuated the pus, and put in a drain. The boy made a good recovery from his desperate condition. Pericardiac surgery in a country homestead by a family practitioner who had not only never previously had any experience of it but had never even seen it performed, and who himself had unaided to make the diagnosis which called for it, indicates a truly high standard of work among practitioners "out back."

Liquid Paraffin and Delayed Dentition

Dr. W. L. ENGLISH (Crewe) writes: From clinical observation babies seem later in cutting teeth than formerly, and when the teeth eventually appear they are often carious and ill developed. One or two doses of calcium and vitamin D subcutaneously show at times an immediate and gratifying acceleration of development in these cases of delayed dentition. It is fairly certain that dentition is a pre-natal issue, possibly as early as the appearance of the enamel and dental germs in the second and third months of pregnancy and embryonic life. The development of these germs depends to a great extent on the environment of the foetus, which is, of course, dependent on the source of nourishment of the foetus—the maternal metabolism. It is generally accepted that the fat-soluble vitamins A and D are necessary for the development of both bone and teeth in the foetus. For the last few years it has become fashionable for pregnant women to take liquid paraffin. The use of this inert substance is insisted on by midwives, and, I fancy, by most ante-natal clinics: expectant mothers would consider it almost a crime if they did not follow the fashion. To what extent has this widespread use of an inert oil been responsible for delayed dentition and caries in deciduous teeth? I understand that liquid paraffin will absorb, and in doing so rob a woman of, the fat-soluble vitamins A and D. So much liquid paraffin ingested, so much fat-soluble vitamin eliminated and lost. If this is fact, the practice of taking liquid paraffin is robbing the foetus of something which is essential to the development of both teeth and bones. Perhaps someone with more knowledge of these matters than I have will give an authorative opinion.

Antibiotic Action of Moulds

Dr. M. COPLANS (Hendon) writes: With reference to the inquiry on this subject by Capt. I. G. Anderson (April 7, p. 504) the following information may prove useful to him as a starting-point for further study: (1) *British Medical Journal,* March, 26, 1927, p. 580. Annotation, "French Experimental Work on Tuberculosis." (2) *Bulletin de l'Académie de Médecine,* Feb., 15, 1927, **97,** No. 7 p. 202, "Nouvelles Recherches sur le Développement du Bacille Tuberculeux. Applications Thérapeutiques," by Drs. A. Vaudremer, E. Puthomme, and J. Paulin. The organism employed appears to be *Aspergillus fumigatus* (not *niger*). There is a reference to Vaudremer's earlier work which appeared in the *Annales de l'Institut Pasteur,* March, 1910. (3) There is also a publication by Dr. Albert Vaudremer, "Le Bacille Tuberculeux. Etudes Bactériologiques, Cliniques et Thérapeutiques," Paris, 1927, Les Presses Universitaires de France. (*Vide* Chap. 20, p. 191, "Traitement par le Liquide de Culture d'*Aspergillus fumigatus* Filtré.") There is an excellent bibliography

Mixed Drinks

Dr. PABLO OSVALDO WOLFF writes from Buenos Aires: Referring to the discussion of "Mixed Drinks and Hangovers" in the *British Medical Journal* of Nov. 11, 1944, I may be permitted to add that the main reason for worse after-effects of cocktails and other mixed drinks than of pure drinks is to be found in the presence of relatively considerable essential oils which mixed drinks very often contain. The same amount of good brandy, in the same concentration, will generally do much less harm than do mixed drinks under equal conditions. The bad effect of those essential (volatile) oils, especially on the heart and the circulation and on the central nervous system, is well known. There exists some literature on the subject; may I quote only one paper written by my late friend Prof. W. E. Dixon, *Brit. J. Inebriety,* 1929, p. 148; another by Brasher, ibid., 1931, **29,** No. 1; G. Guillain, *Bull. Acad. Méd.,* Paris, 1929, p. 538.

Corrigenda

Delay of proofs in the post prevented Major Kendal Dixon from correcting a mistake in his article on "Penicillin and Fibrinolysis" last week. In the second paragraph of column 2 on page 515 the number 1,000,000 units should read 100,000 units.

In the report of the meeting of the Section of Otology of the Royal Society of Medicine (April 7, p. 493) the ranks of the two R.A.F. speakers were incorrectly given. They should be *Air Commodore* E. D. Dalziel Dickson and *Wing Commander* G. H. Bateman.

INTRAVENOUS ARSENIC IN TREATMENT OF ANGINOUS FORMS OF GLANDULAR FEVER

WITH NOTES ON CLINICAL AND LABORATORY DIAGNOSIS

BY

K. SHIRLEY SMITH, M.D., B.Sc., F.R.C.P.

Lieut.-Col., R.A.M.C.; Officer in Charge of a Medical Division

AND

TREVOR H. SHAW, M.B.

Major, R.A.M.C.; Officer in Charge of a Pathological Department

Severe inflammation of the tonsils and fauces in glandular fever may cause serious illness which may even threaten life. It is the purpose of this paper to report the remarkably beneficial effect produced by intravenous injection of arsenic in six examples of this anginous form of glandular fever which have been met with at intervals over a period of 18 months. In general, the treatment of glandular fever is solely palliative, but for this special anginous group arsenic not only produces conspicuous and rapid improvement but may on occasion appear to be life-saving. Case histories illustrating the results of such treatment are recounted, and discussions on other methods of treatment and on the diagnosis and aetiology of the condition follow. For purposes of illustration reference is made to further cases of glandular fever seen during the same period, though not treated with arsenic.

Case I

An officer, aged 21, noticed between June 4 and 8, 1942, that he was sweating at night. This increased during the following week, but he still felt well during the daytime. On June 10 he complained of sore throat for the first time, and during the next 4 days his neck became swollen and stiff. Dysphagia developed, and became so severe that he could swallow liquids only. On June 15 he was admitted to a military hospital. On examination he looked ill and toxic. Cervical glands of the anterior and posterior triangles on both sides were grossly enlarged, giving a bull-neck appearance. Both tonsils were enlarged and inflamed and covered with purulent-looking exudate. A throat swab at this time showed only a few spirochaetes, but no fusiform bacilli or pus cells; culture for *C. diphtheriae* was negative, but there was a moderate growth of a haemolytic streptococcus. 48,000 units of diphtheria antitoxin were given on admission. During the next 48 hours the condition of the patient became grave. There was considerable bleeding from the tonsils. The spleen and axillary glands became palpable. All local and symptomatic treatment was without avail. The result of blood counts on June 16 and 17 are shown in Table I, and the Paul-Bunnell titres on the latter day confirmed the diagnosis. The Kahn test and aerobic blood culture were negative. On June 17 administration of sulphapyridine (10 g. in the first 24 hours) was begun, and at the same time novarsenobillon (M. and B.) 0.45 g. was given intravenously. In 12 hours dramatic improvement was evident, with cessation of tonsillar bleeding and an abrupt fall in temperature and pulse. Everyone who saw the patient was impressed by the rapid transition from an exceedingly grave state to commencing convalescence. Uneventful complete recovery followed.

TABLE I.—*The Haematological Findings in the Anginous Cases I–VIII*

Case	Date	Days from Onset of First Symptoms	Paul-Bunnell Titre	White Cells per c.mm.					
				Total W.B.C.	Neutrophils	Eosinophils	Basophils	Lymphocytes	Monocytes
I	16/6/42	10	—	24,600	9,550	40	50	13,100	1,850
	17/6/42	11	10,240	25,800	12,800	200	200	10,300	2,300
	9/7/42	33	10,240	7,400	3,200	—	—	3,700	500
	1/9/42	87	nil	7,500	3,800	70	40	3,350	240
II	26/8/42	9	80	5,200	2,420	20	40	2,100	620
	27/8/42	10	1,280	15,500	6,400	—	100	8,200	800
	26/9/42	40	320	7,500	2,200	20	80	4,600	700
III	2/9/42	78	640	20,600	6,600	50	50	11,350	2,550
IV	20/3/43	9	—	16,000	2,900	150	150	12,800	
	22/3/43	11	640	12,200	1,200	—	—	4,050	6,950
	28/3/43	17	1,280	6,200	1,050	310	250	4,160	430
V	17/3/43	14	80	5,300	2,760	—	—	1,060	1,480
	23/3/43	22	160	—	—	—	—	—	—
VI	2/6/43	15	640	10,800	3,560	—	108	4,968	2,160
VII	—	12	640	38,000	8,360	100	90	27,550	1,900
	—	33	1,280	4,600	1,290	20	—	3,100	180
VIII	—	19	5,120	21,500	3,750	400	170	16,450	730

NOTES.—The Paul-Bunnell tests were done by the method of Barrett (1941). For the most part, lymphocytes and monocytes appeared to be fully mature. In some films a small proportion of the lymphocytes showed evidence of immaturity of the slight degree quite commonly seen in lymphocytosis of varied origin. Occasional immature monocytes were also seen. Cells with vacuolated cytoplasm or with irregular or deeply indented nuclei were not seen. The majority of the lymphocytes were of the small or medium-sized variety.

Case II

An officer, aged 22, noticed stiffness of the neck and shoulders on Aug. 17, 1942, followed by sore throat and shivering on Aug. 21. He was admitted to a military hospital on Aug. 22. On examination there were glandular enlargements in both posterior triangles of the neck and in the right axilla. Temperature 101.4° F. The tonsils were greatly enlarged and acutely inflamed. A throat swab showed no Vincent's organisms; culture for *C. diphtheriae* was negative and there was an almost pure growth of a haemolytic streptococcus. During the following week intermittent pyrexia to 104° continued, the tonsillar swelling with ulceration and exudate increased, further glandular swellings appeared, and on Aug. 29 the spleen was palpable for the first time. Sulphanilamide therapy was started on Aug. 25, a total of 20 g. being given in 72 hours. A blood count on Aug. 26 showed only an absolute neutropenia; but a Paul-Bunnell titre of 1 in 80 was suggestive, and prompted repeat examinations on the following day, when the count and a titre of 1 in 1,280 established the diagnosis of glandular fever. The Kahn test was negative on Aug. 26. Slight albuminuria was present throughout, and for this reason the administration of arsenic was not at first considered advisable. During the next 10 days the temperature tended to fall and there was a slight improvement in the general condition, but the appearance of the tonsils and the glandular and splenic enlargements were unchanged. On Sept. 6 novarsenobillon 0.15 g. was given intravenously. The small dose was chosen on account of the albuminuria. On the next day the temperature and pulse rate had fallen to normal, the albuminuria ceased, and there was conspicuous subjective improvement. Uneventful and rapid full recovery followed without further injections or local treatment.

Case III

An officer, aged 20, was admitted to a civilian hospital in mid-June, 1942, with "septic throat." A blood count at that time showed W.B.C. 10,000 per c.mm., with neutrophils 19%, lymphocytes 66%, monocytes 15%. A Paul-Bunnell test was not done, and we have no information regarding enlargement of lymph glands or spleen, but the subsequent history suggests that this initial illness was glandular fever. The patient returned to duty at the end of July, though not feeling really well. In mid-August he again complained of sore throat with dysphagia and of neck stiffness and sweating. He came under our observation on Aug. 31, when he was admitted to a military hospital. On examination he did not appear acutely ill. Temperature 100° F. There were groups of enlarged discrete glands in the anterior and posterior triangles of the neck on both sides and in the axillae and groins. The spleen was not palpable at any time. The right tonsil was greatly enlarged and ulcerated, with blood and mucus on its surface. This swelling was so pronounced as to immobilize the soft palate on that side, and swallowing provoked nasal regurgitation of fluids and tonsillar bleeding. A throat swab showed no Vincent's organisms; culture for *C. diphtheriae* was negative and there was only a scanty growth of a haemolytic streptococcus. During the next few days the ulceration of the tonsil developed and deepened and the pyrexia continued though the general condition remained much the same. A blood count and a Paul-Bunnell test on Sept. 3 established the diagnosis of glandular fever. No benefit had followed local and symptomatic remedies, and on Sept. 4 novarsenobillon 0.15 g. was given intravenously. On the following day the temperature had fallen to normal and the tonsillar swelling had diminished. After a further 24 hours the tonsillar swelling and exudate had completely disappeared, and rapid convalescence with full recovery followed. No sulphonamide drug was given in this case.

Case IV

A gunner, aged 22, developed sore throat and swelling in the neck on March 12, 1943. He was admitted to a military hospital on the same day. On examination the tonsils were considerably enlarged and the fauces swollen and red. There was no exudate. Large glands were palpable below the left angle of the jaw. The next day there was a membrane on the left tonsil. 32,000 units of diphtheria antitoxin were given and at the same time administration of sulphapyridine was started, a total of 19 g. being given during the next few days, during which the local throat condition remained unchanged and there was continued pyrexia. On admission a throat swab showed large numbers of Vincent's organisms; culture for *C. diphtheriae* was negative. On March 17, when sulphapyridine was discontinued, sulpharsphenamine 0.45 g. was given intravenously. On the following day the temperature was normal and it remained so, rapid subsidence of the throat condition taking place. On March 19 the spleen was palpable and there was an enlargement of axillary, inguinal, and epitrochlear glands. Facilities for further laboratory investigations now became available, and blood examinations on March 20 and 22, together with a Paul-Bunnell test on the latter day, confirmed the diagnosis of glandular fever.

Case V

An officer, aged 28, developed sore throat with swelling of glands on both sides of the neck on March 4, 1943. After 48 hours' treatment with sulphapyridine and local applications the condition appeared to subside completely. It recurred on March 15, and he was admitted to a military hospital on the 17th. On examination he looked ill. Temperature 100.5° F. There were discrete enlarged glands in both posterior triangles, especially in the suboccipital region, and also in the anterior triangles, axillae, and groins. The spleen was not felt. Both tonsils were greatly enlarged, almost meeting in the midline, and showed ulceration with yellow sloughs on their medial aspects. A throat swab showed no Vincent's organisms; cultures for *C. diphtheriae* and for haemolytic streptococci were negative. The blood picture was suggestive of glandular fever, but a Paul-Bunnell titre of 1 in 80 was inconclusive. Progressive deterioration in the general condition followed during the next few days, with remittent pyrexia to 103° F., severe dysphagia, and bleeding from the throat. On March 20 novarsenobillon 0.3 g. was given intravenously. By the same evening there was considerable subjective improvement, and after a further 24 hours the swelling of neck and throat and the tonsillar bleeding had greatly diminished. The spleen was palpable on March 21. During the next few days swelling of the throat further diminished and the patient was able to eat soft food. The sloughs on the tonsils persisted, with further profuse bleeding on March 23, and as remittent pyrexia also continued a further 0.3 g. of novarsenobillon was given intravenously on March 26. On March 30 the throat was completely normal in appearance and the spleen and glands in axillae and groins were no longer palpable, and only a few glands could be felt in the neck. The temperature fell by lysis after the second injection and remained normal after April 1. On March 23 a blood count showed a pronounced mononucleosis and a Paul-Bunnell test a rise in titre to 1 in 160.

Case VI

An officer, aged 37, was admitted to a military hospital on June 1, 1943, complaining of weakness, general malaise, and sweating. About a fortnight previously he had had coryza, with left-sided sore throat and dysphagia. On examination he was feverish (temperature 99°-100° F.) and the throat showed an enlarged and inflamed left tonsil: there was an ulcer with a sloughy base. There were only one or two small glands in the posterior triangles, but enlarged groups of glands were present in both axillae. The spleen was easily felt, and was firm. A papular rash was present over the trunk and buttocks. A throat swab showed many Vincent's organisms. Cultures for *C. diphtheriae* and for haemolytic streptococci were negative. On June 2 the blood count and a Paul-Bunnell titre of 1 in 640 established the diagnosis of glandular fever. A blood count showed 4.5 million red cells, 100% Hb, and 10,800 white cells, of which 33% were polymorphs, 46% lymphocytes, 20% monocytes, and 1% basophils. The Paul-Bunnell test was positive at 1 in 640. On June 4 the glands in the neck were larger, fever was persisting, and the splenomegaly and the rash were unchanged. Intravenous novarsenobillon 0.3 g. was given at noon: within 6 hours there was a diminution of pain and dysphagia, and on the next day the temperature dropped to normal. During the succeeding days the throat healed, the rash faded, and the spleen became smaller. The patient was discharged from hospital on June 14.

Cases VII and VIII

These were mild anginous cases which were under observation concurrently with the first three. They presented no exceptional clinical features and did not receive treatment by arsenic. Accordingly no further description is given, but their haematological findings have been tabulated for purposes of illustration.

Local Treatment of Very Severe Throat Infections

The throat lesions of the anginous type of glandular fever may be among the most severe that can be encountered. Not only may there be massive oedema accompanying the acute inflammation of the tonsils and neighbouring structures, but these may become extensively ulcerated; considerable bleeding may ensue. Bronchopneumonia may develop and bring about a fatal issue. Severe dysphagia often occurs, militating against the full fluid intake so desirable in acute febrile illnesses. In addition, if the lesion is unilateral it may cause asymmetrical dysfunction of the soft palate with resulting regurgitation of fluids through the nose. In these circumstances local treatment becomes a matter of concern.

Scrupulous attention to cleansing of the throat, teeth, and gums was the first essential. No benefit was to be obtained from the usual gargles, such as eusol 1 in 4 solution or Milton fluid, nor from Mandl's paint. It seemed that swabbing with hydrogen peroxide (10 vols.) was the most effective local treatment in the acute stage, while applications of hot cotton-wool or of kaolin eased the pain in the neck. After the very acute stage, and for residual ulceration of the tonsils, a paint made up of equal parts of liq. arsenicalis and tinct. ipecacuanhae was the most effective local application. In throat lesions of this severe order fluids had to be given neither hot nor very cold. In none of our cases was the reduction of fluid intake through dysphagia sufficiently prolonged to necessitate rectal or intravenous infusions. It was important to avoid any medicine containing piquant flavouring agents such as peppermint or ginger. Irritant solutions had to be avoided, and the well-known Army "three fifteens," containing sod. brom. 15 gr., chlor. hydras 15 gr., and tinct. opii 15 m., could not be employed. Morphine 1/4 gr. by injection had at times to be used to induce sleep.

The Use of Intravenous Arsenic

It is evident from the foregoing histories that arsenic was employed in Case I with the aim of countering a Vincent's infection which was believed to be complicating anginous glandular fever. The seeming beneficial effect of the drug in this case prompted its experimental use in Cases II and III even though no Vincent's organisms had been found in the throats. In both, rapid subjective and clinical improvement resulted, and substantially similar results followed the same therapy in the remaining cases. In view of the small number of cases treated in this way, and in the absence of any controlled observations, impressions alone and not definite conclusions are the result. We are aware that in many instances a termination of the condition by crisis does occur, and that there is great variation in the severity and duration of illness in different cases. But in all the cases described here the immediate improvement in the patient's local and general condition, and the marked subjective improvement upon which all the patients themselves commented, do render it difficult to escape the conclusion that the arsenic was greatly beneficial. We find ourselves unable to offer any explanation of its mode of action, for the apparent effect did not extend to other manifestations—e.g., glands and spleen continued to enlarge in some cases, and it is interesting to note that in Case IV the Paul-Bunnell titre continued to rise.

Observations on the Diagnosis of the Condition

The diagnosis of glandular fever is usually not difficult. The disease is suspected more often than it exists, but, in general, strong clinical indications are followed by haematological confirmation. Certain relevant points emerge from consideration of these cases.

1. *History.*—In nearly all cases of glandular fever the history reveals some days of malaise before the onset of the acute illness. It is not uncommon for a patient to mention a recent feverish illness, with or without sore throat, from which an incomplete recovery has been made—e.g., Cases III, V, and VI. Sweating is usually a conspicuous symptom, and may even be the patient's principal complaint.

2. *Glandular Enlargements.*—Posterior triangle glandular enlargements are suggestive in association with sore throat, but if there are no other glandular enlargements the diagnosis is not likely to be established. The natural reluctance to examine the axillae thoroughly in feverish patients should be set aside, since with considerable glandular enlargement here the diagnosis becomes much more probable. The glands in the groin are rarely of diagnostic help unless they are enlarged to a very considerable degree.

3. *Throat Inflammations.*—The suspicion of glandular fever should be aroused in any severe inflammation or ulceration of the fauces in which the findings on microscopical and bacteriological examination of swabs are insufficient to account for the condition—e.g., Cases I and III. Conversely, in some cases the bacteriological findings appear at first adequately to account for the condition of the throat and so obscure the diagnosis—e.g., Case II, in which a pure growth of haemolytic streptococci was obtained, and Case IV, in which large numbers of Vincent's organisms were found.

4. *Blood Cytology.*—Table I illustrates well the wide range of variation which may be met with in the total and differential leucocyte counts, and it is evident that no one diagnostic picture can be described. Further to illustrate the variations which may occur, a case of "glandular" type (Case A, Table II) seen subsequently in an adult showed 3,000 per c.mm. of lymphoblasts and monoblasts out of a total white cell count of 32,000 per c.mm.: at a subsequent count a week later these cells had completely disappeared. While in general some fairly marked departure from the normal is encountered, the blood picture may at first fail to suggest the possibility of glandular fever. It is well for the clinician to bear this in mind in the interpretation of blood counts on cases which are clinically suggestive. In these anginous cases the important feature was a departure from normal in a direction other than the absolute neutrophilia which one would expect in a severe septic throat. Such a finding should certainly prompt repeat counts to determine the maximum mononuclear cell increase.

5. *Paul-Bunnell Tests.*—Whatever may be the significance of the agglutinins for sheep erythrocytes which are developed in this disease, demonstration of their presence in appreciable titre is still an essential factor in diagnosis. Attention is drawn to the following features: (1) In cases seen by the 12th day or earlier a diagnostic titre of agglutinations had already been reached. The very high level of 1 in 10,240 on the 11th day in Case I and its maintenance after a further 22 days is particularly noteworthy. (2) Case II, showing a titre of 1 in 80 on the 9th day and 1 in 1,280 on the following day, illustrates the rapid rise which may occur and emphasizes that repeated estimations of titre may be necessary. (3) In general there was no correlation between the titre attained and the severity of the illness; but the fact that a rapid increase may occur in a short time probably renders this observation invalid in the absence of serial daily determinations. (4) The importance of the absorption tests with guinea-pig kidney extract and autoclaved ox erythrocytes is well illustrated by Case I. In this the final test on the 87th day of the disease gave an unabsorbed titre of 1 in 320, but the agglutinations were completely absorbed by ox-cell suspension and are not to be regarded as of glandular fever type; the titre is accordingly recorded as *nil.*

6. *Response to Therapy.*—Any beneficial action of sulphonamides in glandular fever is exceedingly doubtful, as indeed might be expected if the disease is in fact due to a virus. In this series Cases II and IV received such therapy with no improvement; and Kilham and Steigman (1942) record the same lack of response in five anginous cases. In any acute throat condition treated by sulphonamides without response the possibility of glandular fever should be borne in mind, especially in cases in which a presumably sulphonamide-sensitive organism is present in large numbers (e.g., Case II). In the Army over-seas, the possibility of faucial diphtheria, often presenting atypical features, is of course ever in mind and carefully excluded. Our claims for the beneficial action of arsenic in these severe anginous manifestations of glandular fever may be contested on the ground that they were in effect examples of Vincent's angina superimposed upon glandular fever and that the favourable course was but a substantiation of the merits of the conventional treatment of Vincent's infection. But only three of the cases showed microscopical evidence of Vincent's infection, and the response in the other cases was similar in kind and degree. This prompts the reflection that many cases diagnosed as Vincent's angina, might on further investigation be revealed as cases of anginous glandular fever.

Changes in Bone Marrow

The neutropenia present in many of these cases prompted inquiry into changes in the bone marrow. Sternal puncture was accordingly performed on two cases of mild glandular type. The blood changes in one of these has been previously referred to. The differential counts on the marrow cells are recorded in Table II together with the results of white blood counts taken at the same time. (The classification of the cells has been condensed for the sake of brevity.)

Both marrow smears showed an approximately normal degree of cellularity. It is noteworthy that the highly abnormal blood picture in Case A is not reflected in the marrow. The somewhat high myeloblast count in both suggests a disturbance of granulopoiesis. That this is probably a maturation defect at the myeloblast level is indicated in Case B by the diminution in numbers of more mature myeloid cells—an observation which coincides with the marked blood neutropenia. The normal erythropoiesis is in accord with the customary absence of anaemia usual in these cases.

It is regretted that circumstances were unfavourable to the carrying out of sternal puncture on some of the severe anginous cases. The determination of the degree and level of the marrow defect in such cases would have been of great interest in view of their similarity to agranulocytic angina in some points. It may be noted, however, that the neutropenia in Case B was as pronounced as any met with in our anginous cases.

Table II.—*The Blood and Marrow Findings in Two Further Cases of Mild Glandular Type*

Marrow			Blood		
	Case A	Case B		Per c.mm.	
				Case A	Case B
	%	%	Total W.B.C. ..	32,000	17,000
Segmented polymorphs	18·0	8·4	Neutrophils ..	5,250	1,200
			Lymphocytes ..	21,250	14,450
Metamyelocytes ..	23·2	13·4	Monocytes ..	2,560	1,180
Myelocytes ..	19·2	11·2	Lymphoblasts and monoblasts	2,940	170
Premyelocytes ..	8·2	8·2			
Myeloblasts ..	6·2	9·6			
Lymphocytes ..	13·0	15·2			
Monocytes ..	0·6	5·4			
Haemocytoblasts ..	0·4	2·2			
Erythroblasts ..	3·0	6·6			
Normoblasts ..	8·2	19·8			

Observations on the Aetiology of the Faucial Ulceration in These Cases

Glandular fever presents many diverse signs, and in general this may be ascribed to the great variation in the amount and situation of the lymphoid hyperplasia throughout the body. It is indeed remarkable that in a generalized septicaemic infection such as this, whose dominant feature is lymphoid hyperplasia, many areas of lymphoid tissue appear to escape relatively unaffected. There is a tendency to regard anginous glandular fever as a distinct type, whereas rather would it seem to be a fortuitous manifestation of a general infection depending upon the occurrence of a maximum degree of hyperplasia in the lymphoid tissue of the fauces with subsequent ulceration of the overlying mucosa.

It has been seen that neutropenia of some degree was present in all our cases at some stage of the disease, and Kilham and Steigman (1942) report a similar finding. It has been suggested that this neutropenia bears a direct aetiological relationship to the occurrence of faucial ulceration—that the lesions are in fact of similar nature to those seen in agranulocytic angina. Against this view the following points may be mentioned: (1) The neutropenia is not confined to the anginous type of the disease. (2) In no case did it amount to the complete or nearly complete disappearance of neutrophils seen in agranulocytic angina. (3) Neutropenia of the same intensity as that seen in many of these cases—perhaps even a greater intensity—is observed in many conditions of which faucial ulceration is not a feature. (4) The stage of the disease at which it was observed in our cases varied greatly and in general could not be correlated with the condition of the throat: for example, Case I, one of the most severe, showed a neutrophilia during the worst phase, a moderate neutropenia appearing later; while in Case IV healing occurred despite the persistence of a severe neutropenia. (5) In agranulocytic angina there is evidence of long-continued neutropenia before the onset of faucial ulceration. The same may be the case in glandular fever, but in general the period of malaise before the faucial ulceration starts is relatively short, though it seems a more likely occurrence in the "double" or relapse type of illness seen in Cases II and V. If neutropenia does occur it no doubt facilitates the invasion of broken surfaces by secondary bacterial invaders, and so the initiation of a further degree of neutropenia by sulphonamides might adversely affect the outcome. Hence we consider that sulphonamide therapy is absolutely contraindicated in all cases of glandular fever, for a greater degree of neutropenia so induced may facilitate the development of the anginous form as the disease progresses. A possible example of this occurrence is Case V.

On the available evidence our conclusion is that neutropenia plays probably only a secondary part and is not in itself the cause of the ulceration. Further studies are needed for elucidation of this point. Blood and marrow studies during interim periods, such as were observed in Cases II and V, might yield information of interest

Summary

Among patients with anginous forms of glandular fever are to be found some of the severest throat infections encountered in medical practice. Acute inflammation with purulent exudate, oedema, ulceration, haemorrhage, and mechanical interference with the action of the soft palate may severally be present.

Six patients suffering from anginous glandular fever were treated with intravenous arsenicals. Speedy and conspicuous benefit was obtained.

The haematological findings in these and other cases are tabulated and discussed. In cases seen before the 12th day a conclusive diagnostic titre of agglutinations had already been reached.

The general treatment and management of very severe throat infections are considered.

Diagnosis is reviewed briefly from the standpoints of history, glandular enlargement, throat inflammation, haematology, and response to drugs.

Neutropenia was present at some stage in each of our cases. Its significance is discussed. Since sulphonamides are apt to cause neutropenia they are contraindicated in this disease.

Our thanks are due to Major G. L. Robinson, R.A.M.C., for carrying out laboratory investigations in Cases IV, V, and VI.

(It is regretted that the exigencies of oversea service have prevented fuller access to the literature.)

H. H. Clemens (*J. Pediat.*, 1945, **26**, 66) records his observations on 80 cases of exanthema subitum (roseola infantum), of which 42 were in boys and 38 in girls. Most occurred in February, March, April, and October. The disease is characterized by an abrupt onset, malaise, and termination in an afebrile exanthem. Fever, irritability, and slight enlargement of the lymphatic glands are typical in the eruptive stage. Complications are very rare. The blood shows relative leucopenia and neutropenia with lymphocytosis by the third day of disease.

POTENT ANTI-Rh AGGLUTININS DEVELOPED IN AN Rh-NEGATIVE FEMALE AFTER MULTIPLE TRANSFUSIONS OF Rh-POSITIVE BLOOD*

BY

R. DRUMMOND, M.R.C.S., L.R.C.P.
Transfusion Officer, Welsh Board of Health, Cardiff

G. L. TAYLOR, M.D., Ph.D., F.R.C.P.
Medical Research Council Serum Unit, Cambridge

AND

J. T. RICE EDWARDS, F.R.C.S.
Honorary Surgeon, Royal Gwent Hospital, Newport

In the case here reported iso-immunization to the Rh factor followed repeated blood transfusions and resulted in haemolytic reactions of varying degree and in the development of anti-Rh agglutinins of exceptionally high titre in the serum of the recipient. The recipient was Group O, as were all the donors. All ABO blood-grouping and cross-matching tests were performed in tubes (5 cm. by 1 cm.). In the cross-matching tests equal volumes (0.4 c.cm.) were used of serum, citrate-saline, and citrated cell suspensions of 0.5% strength in terms of cell sediment. Mixtures were stood five minutes and then centrifuged at 1,500 revs. per min. for two minutes. Readings were made with the naked eye after adequate agitation of tubes. Blood groups were always tested on cells and serum. In cross-matching tests the recipient's serum was tested against the donor's cells, and the donor's plasma against the recipient's cells. In Rh investigations the tube technique described below (on p. 586) was used.

Case History

An unmarried woman aged 47 sought medical advice in April, 1943, because of increasing lassitude and pain in shoulders and elbows. She had recently had a "chill." On April 29 she had a severe bout of melaena and pain in her abdomen, left side of chest, and knees. There was no fever. The Widal reaction was negative. On the 30th she had a haemoptysis. Purpura now appeared on the limbs and trunk. On May 1 the blood count was: red cells, 1,552,000; platelets, 144,000; leucocytes 19,800. Haemoglobin 36%; coagulation time, 2½ minutes; bleeding time, 12 minutes. Her last menstrual period began on May 3, and lasted 16 days; the loss was profuse. The spleen was not palpable. Her previous medical history was unimportant. The patient had never had a blood transfusion and had never been pregnant. In spite of the platelet count a very tentative diagnosis of thrombocytopenic purpura was made. It was decided to give blood transfusions to raise the haemoglobin to a level high enough to permit of splenectomy. At this time the Rh group of the patient was not ascertained. Concentrated red-cell suspensions only were used in the 10 transfusions reported below. All transfusions were given at very slow drip rates. Blood older than eight days was not used. The standard mixture of donors' blood from which concentrated red-cell suspensions were prepared was: whole blood, 400 c.cm.; glucose, 20 c.cm. of 15% solution: and sodium citrate, 120 c.cm. of 2.5% solution. The sequence of events was as follows, dating from the first transfusion given on May 1.

1st Day.—First transfusion. Given 450 c.cm. (two donors). No febrile reaction. Later, one donor was found to be Rh+, but the other was never traced.

2nd Day.—Second transfusion. Given 450 c.cm. (two donors). No febrile reaction. Both donors later found to be Rh+. Cross-matching tests for the first two transfusions showed compatibility Marked improvement followed these transfusions.

3rd Day.—The patient had a severe vaginal haemorrhage, but, despite this, was much better. On the 4th day the R.B.C. was 3,720,000 and the Hb 66%; next day the Hb had fallen to 60%.

6th Day.—Third transfusion. Red cells were prepared from two donors, both subsequently found to be Rh+. When 200 c.cm. had been given the patient had a rigor. Transfusion was promptly stopped. The temperature rose from 99 to 103° F. No improvement. On the 8th day the Hb had dropped to 46% and the R.B.C. to 2,480,000. On the 9th day the patient suffered from retinal haemorrhages. On the 11th day multiple ecchymoses appeared on the trunk and there was a profuse epistaxis. A specimen of blood collected from the recipient on the 9th day was now referred for investigation. In respect of the third transfusion a pre-transfusion sample of the recipient's blood had been conserved in cold storage, as had samples of blood from both donors. Cross-matching tests were repeated, using all these specimens, but no incompatibility was detected with the tube-centrifuge technique described above. The specimen of recipient's blood collected on the 9th day was tested for the Rh factor, and the cells gave a good positive reaction. No irregular agglutinin was detected in the serum.

---

* This article came into our hands when the untimely death of one of the authors—Dr. G. L. Taylor—was announced.

13th Day.—R.B.C., 1,696,000; Hb 35%; platelets 52,000. Clinical condition suggestive of infective endocarditis.

14th Day.—Fourth transfusion. Given 500 c.cm. (two donors). No febrile reaction. The sample of recipient's blood collected on the 9th day was used in the cross-matching tests, which showed compatibility. General condition improved. The donors were never traced, so that their Rh groups are not known.

17th Day.—R.B.C., 1,992,000; Hb 46%. A specimen of the recipient's blood was collected and used in cross-matching tests for the next two transfusions; no incompatibility detected.

20th Day.—Fifth transfusion. A suspension of 500 c.cm. of red cells was prepared (two donors). Transfusion stopped when 250 c.cm. had been injected, because the needle slipped out of the vein. No febrile reaction. Later, one donor was found to be Rh-negative, but the other was never traced.

21st Day.—Sixth transfusion. The 250 c.cm. remaining in the bottle used the previous day was given. In addition 450 c.cm. of red cells (two donors) was given; both donors later found to be Rh+. No febrile reaction. Some hours after transfusion the patient had pains in her knees, but she had had similar pains previously. Two days later she had pains in the back and knees. A radiograph of the spine was negative.

28th Day.—Acute pleurisy with audible rub developed on left side. No cough or haemoptysis. General condition fair. Some irregular pyrexia.

33rd Day.—R.B.C., 3,120,000; Hb 53%.

38th Day.—R.B.C., 2,560,000; Hb 50%.

43rd Day.—R.B.C., 1,696,000; Hb 26%. This fall was probably in part due to the very severe purpura present.

44th Day.—Seventh transfusion. Given 450 c.cm. (two donors). Later, one donor was found to be Rh-negative, but the other was never traced. The specimen of recipient's blood used in the cross-matching tests was collected the day before transfusion, and no incompatibility was detected. When nearly all the blood had been given the temperature rose sharply from 98.4 to 104° F. The patient had, however, been running a slight irregular pyrexia. The pulse rate rose from 128 to 136. The general condition rapidly deteriorated, and for some hours the patient was delirious. Next morning there was slight jaundice, which lasted a day only. The urine was a deep orange colour but apparently otherwise normal. Four days later the R.B.C. was 2,384,000 and Hb 34%.

51st Day.—Eighth transfusion. Given 480 c.cm. (two donors). Cross-matching tests, using a sample of the recipient's blood collected three days previously, revealed compatibility. Subsequent tests showed one donor was Rh+ and the other Rh-negative. Soon after transfusion the recipient became very restless and her condition deteriorated seriously. The temperature rose from 101 to 102° F. and the pulse became rapid and thready. A few ounces of dark urine were passed shortly after transfusion, and a note was made that blood was present in the urine. A second specimen of dark urine was voided half an hour after the first, but it was not so dark. Two hours later more urine was voided; though still dark, it was much clearer than the first two specimens. Subsequent specimens of urine were of normal appearance. Either the second or the third of the dark specimens of urine was examined with a spectroscope, but no haemoglobin was detected. It seems probable that the first specimen of dark urine contained haemoglobin. Tests for bile salts and pigments were negative. Three days after transfusion the Hb was still 34%, but the R.B.C. had fallen to 1,969,000.

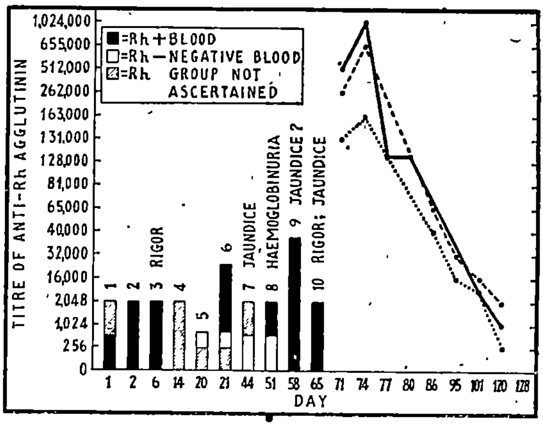
58th Day.—Ninth transfusion. Given 900 c.cm. of red cells from four donors, all later found to be Rh+. Cross-matching tests, using a specimen of the recipient's blood collected two days previously, revealed no incompatibility. Nothing untoward noted during transfusion (which took over six hours), but soon after transfusion the recipient was restless, irrational, and incoherent. The temperature rose from 100 to 103.4° F. and the pulse became rapid and feeble. Next morning there was a suggestion of jaundice, but nothing definite. Urine normal. Three days later the R.B.C. was 1,616,000 and Hb 26%. The large-volume transfusion of red cells had been without beneficial effect. Patient now very anaemic. Numerous petechiae and ecchymoses present. Spleen just palpable.

65th Day.—Tenth transfusion. 450 c.cm. of red cells prepared (two donors). Both donors subsequently found to be Rh+. No cross-matching tests were carried out at the transfusion laboratory, since a recent specimen of the recipient's blood was not available. However, a sample of her blood was collected immediately before starting transfusion, and a cross-matching test by the slide technique was performed while transfusion was in progress. Distinct agglutination of the donors' corpuscles was observed. A message was then received that 200 c.cm. of blood had been injected and that the recipient was having a rigor and had pain in the occipital region. Transfusion was immediately stopped. The temperature rose from 98 to 101° F. Next morning there was slight transient jaundice.

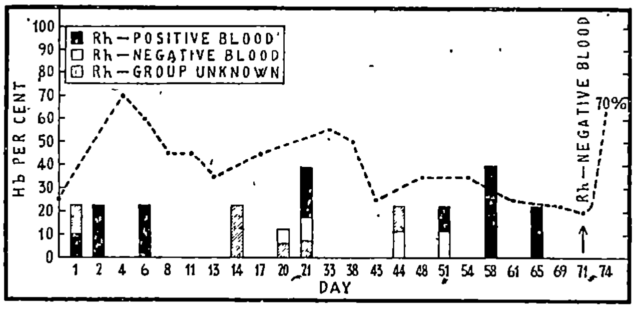
66th Day.—Further investigations requested. The pre-transfusion sample of the recipient's blood was referred for investigation. Specimens of the donors' bloods had been conserved. Cross-matching tests were carried out by the tube-centrifuge technique and the donors' cells were agglutinated into solid clumps which vigorous shaking of the tubes failed to disrupt. The donors' plasma did not agglutinate the recipient's cells. Recipient's and donors' groups were confirmed as O. The recipient's serum was then tested by the tube-centrifuge technique against the cells of 46 Group O persons, and 36 of these were strongly agglutinated. Relaxation of the rule that concentrated red cells should not be issued without preliminary cross-matching tests, using a fresh sample of the recipient's blood, resulted in the incompatibility being missed, and nearly had serious consequences for the patient. Blood urea, 75 mg. per 100 c.cm. Urine normal. Four days after transfusion the Hb had fallen to 22% and the red cells to 1,248,000.

71st Day.—Further tests revealed that the recipient was in fact Rh-negative and that her serum contained a potent anti-Rh agglutinin, with a titre of 1: 512,000. The technique of titration was that described by Taylor and Race (1944).

Efforts were forthwith made to trace all donors used in the transfusions, in order to ascertain their Rh groups, and these have been given above. Independent serial titrations of the recipient's serum were carried out against the cells of three Group O Rh+ donors (see Graph 1). A maximum titre of 1: 1,024,000 was attained on the 74th day—i.e., on the ninth day after the tenth transfusion. The effects of the various transfusions on the haemoglobin level are shown in Graph 2. In tests against the cells of 1,674 Group O persons the recipient's serum agglutinated 1,404 (84%) and reacted negatively with 270 (16%).



GRAPH 1.—Serial titrations of anti-Rh agglutinin in recipient's serum against cells of three known O Rh+ persons. The maximum titre was attained on the ninth day after the last transfusion of Rh+ blood, and thereafter steadily declined.



GRAPH 2.—The curve shows haemoglobin level during the period when transfusions of Rh+ blood were given.

Subsequent blood transfusions were uneventful. A further 14 transfusions were given, involving the blood of 27 Rh-negative donors. Improvement followed every transfusion and there were no febrile reactions. The haemoglobin was raised from 29 to 70%.

These transfusions rallied the patient temporarily, but ultimately her condition rapidly deteriorated. Petechiae and ecchymoses constantly appeared in various situations, and profuse haemorrhage occurred at times per vaginam. Gradually the patient became emaciated, and ultimately, since treatment was of no avail, transfusion therapy was discontinued. The patient died on the 128th day.

Necropsy was performed by Dr. W. Panes, assistant county pathologist for Monmouthshire. The primary disease was lymphadenoma, the distribution of which was confined to the liver, gastrohepatic lymph glands, and ovaries. Multiple ecchymoses were present in the tissues, which were oedematous. The spleen weighed 1 lb. and was engorged. The liver was not enlarged, and contained much deposit of iron. The kidneys were normal macroscopically, but were not examined histologically. The uterus was slightly enlarged and several fibromyomata were present.

Discussion

The first three transfusions were given on the first, second, and sixth days respectively, and five of the six donors used were Rh+, while the Rh group of the sixth is not known. The original Rh+ diagnosis was made on the third day after the third transfusion, and was certainly due to large numbers of surviving cells of the Rh+ donors in the recipient's blood. Differential agglutination tests (see Wiener, 1942, and Mollison, 1943) might have revealed the true diagnosis, but as so much Rh+ blood had been transfused this is doubtful. In the event, the Rh+ diagnosis induced a false sense of security, in no way lessened by the fact that the next three transfusions were not complicated by febrile reactions (although two at least of the six donors used were Rh+) and no incompatibility was observed in the cross-matching tests. The reaction complicating the third transfusion was possibly haemolytic in nature, since there was no subsequent rise of haemoglobin. Haemolytic reactions complicated the seventh, eighth, ninth, and tenth transfusions. However, for the above-mentioned reasons, and because of the clinical condition of the patient, the significance of these reactions was not at first apparent. Only in retrospect did the position become clear. It was because of the reaction and the agglutination observed in the cross-matching tests (by the slide method) in the tenth transfusion, and the failure of the patient to improve despite transfusions, that further investigations were requested. Only when the Rh-negative diagnosis was made and the anti-Rh agglutinin discovered in the recipient's serum was the whole history reviewed and the facts as outlined above placed in their true perspective.

Cross-matching by the tube-centrifuge technique probably explains why incompatibility was not detected earlier. DeGowin (1938) reported a haemolytic transfusion reaction (Case 6) in which cross-matching tests by the tube-centrifuge technique did not reveal incompatibility. The recipient and donors belonged to Group A, and in the light of present knowledge it is probable that immunization to the Rh factor was involved. The tube-centrifuge technique is eminently satisfactory for rapid blood-grouping and cross-matching tests in the ABO system, but it certainly does not suffice in cross-matching tests when very weak anti-Rh agglutinins are present in the recipient's serum, and especially if tubes are stood only for a few minutes before being centrifuged; when, however, the Rh antibodies are strong, the tube-centrifuge technique is satisfactory (Drummond—personal observations). To detect incompatibility due to anti-Rh agglutinins the cross-matching tests should be performed by the following method.

Equal volumes (about 0.05 c.cm.) of serum and of red-cell suspension (0.5–1% in terms of sediment) are mixed in a small tube; 2 in. by 1/4 in. precipitin tubes serve well. In the great majority of cases agglutination due to Rh cannot be detected by the slide or tile method commonly used for ABO grouping. In addition to the cells of intended donors the recipient's serum should, whenever possible, be tested against, say, four or five lots of Rh+ cells known to be strongly reacting and against control Rh-negative cells. Serum and cell suspension are mixed by flicking the tube with the finger. Capping or corking the tubes will prevent evaporation. Readings are made after an hour at 37° C. Some of the cell sediment is carefully drawn up the stem of a Pasteur pipette and spread gently and evenly on a microscope slide and examined for agglutinates under a low power. In a negative reaction the cells are free and evenly distributed, but aggregation due to sedimenting may be mistaken for true agglutination.

The serum of the case here reported was of the ordinary 85% type, which contains one agglutinin, and had, in addition to complete or agglutinating antibody, some of the recently described "incomplete" (Race, 1944) or "blocking" antibody (Wiener, 1944). It is possible, but very unlikely, that the earlier direct tests of the patient's serum and the donors' cells failed to disclose incompatibility, because the antibody was then mostly or entirely of the incomplete sort.

There is another probable reason why incompatibility was not detected earlier—namely, that the anti-Rh agglutinins, initially only weak, would be completely absorbed by the substantial amounts of Rh+ cells transfused. Therefore, for an interval after each transfusion no anti-Rh agglutinin would be detectable in the recipient's serum.

Cases have been reported (Wiener and Peters, 1940; Boorman *et al.*, 1942; Diamond, 1942; Wiener *et al.*, 1942; Dameshek and Levine, 1943; Mollison, 1943; Beck *et al.*, 1944) in which serious or fatal haemolytic reactions complicated only one or a few transfusions of Rh+ blood in Rh-negative recipients. In the above case, despite the tremendously potent Rh antibodies (titre 1 : 1,024,000) present in the recipient's serum so soon after the tenth transfusion, and the substantial amounts of Rh+ blood transfused (14 donors were Rh+, 3 Rh-negative, while the Rh groups of 5 are unknown), symptoms during the majority of the transfusions were entirely absent. Thus, except for a rigor during the third transfusion, the first six transfusions were entirely symptomless, while the seventh was practically completed before symptoms, not especially severe, occurred. Symptoms were entirely lacking during the eighth and ninth transfusions, though they afterwards became manifest. Yet in the ninth transfusion no less than 900 c.cm. of red cells was given (4 Rh+ donors!). The rigor was not severe in the tenth transfusion. Nevertheless, haemolysis certainly occurred in the seventh, eighth, ninth, and tenth transfusions, as evidenced by jaundice or haemoglobinuria and the fact that there were no surviving Rh+ cells shortly after the tenth transfusion. It is also noteworthy that the haemolytic reactions were not followed by suppression of urine. The urine was alkalinized as a routine by large doses of potassium citrate given by mouth. It is likely that absence of alarming symptoms during practically all the transfusions was due to the fact that the transfusions were all given at very slow drip rates, the duration of each transfusion being usually anything from four to seven hours or more. The lessened severity, or indeed even total absence, of symptoms when incompatible blood has been transfused at a slow drip rate has been alluded to by Mollison (1943) and by Drummond (1944); see also reports by Boorman *et al.* (1942, Case 1) and Burnham (1930).

Conclusion

The above case illustrates the importance of (i) ascertaining the Rh group of a recipient as a preliminary when multiple blood transfusions are contemplated; (ii) the possible danger of being misled when an Rh-negative recipient's blood gives an Rh+ reading after a blood transfusion; (iii) never omitting cross-matching tests, which should be made in tubes by a reliable method.

A. Bloxsom (*J. Pediat.*, 1945, **26**, 32) records his observations on 40 persons—2 adults and 38 children—injected intradermally with recent convalescent measles serum. The serum was given in 0.4-c.cm. doses on successive days until 2 c.cm. had been given. The results were as follows: 35 children and 2 adults did not develop measles; 2 children developed uncomplicated measles before the course was completed, and 2 children developed attenuated measles fourteen days after the inoculations.

THE WAR-DISABLED

THEIR EMOTIONAL, SOCIAL, AND OCCUPATIONAL SITUATION

BY

E. WITTKOWER, M.D., L.R.C.P.Ed.
Major, R.A.M.C.

One of the chief tasks incumbent on a nation at war is to look after those of its citizens who have been severely disabled in the service of their country. For the uninformed this is merely a surgical and financial matter, but the informed have long known that the working capacity and social readaptation of the disabled man do not exclusively depend on his physical condition. To a large extent they depend on his state of mind. An able-bodied man who goes out to fight and comes back badly maimed encounters a variety of problems arising from his disability; according to his temperament and character he either is able to solve them or fails. If he fails he creates a good deal of unhappiness for himself and those around him, and eventually he may become a liability to the community. While great strides have been made in many aspects of the after-care of the disabled, it is felt that the psychological aspect has so far received insufficient attention.

What follows is a summary of detailed reports on each of the disabilities studied—loss of limb, blindness, loss of vision in one eye. Considerations of space necessitate omission of much of the confirmatory and explanatory evidence. 200 amputees, 103 war-blinded, and 102 monocular individuals were examined psychiatrically, each of them for at least two hours. Characteristics common to all three types of disabled men, and differences in their emotional, social, and occupational situation specific for each of the disabilities, are discussed.

I. EMOTIONAL SITUATION

A. Common Characteristics

Common Psychological Features.—Severely disabled men, irrespective of the specific nature of their disability, are apt to regard it as a defect which lowers their status in the eyes of their fellow citizens. In extreme cases, sometimes with but more usually without foundation, the men are afraid that they may become an encumbrance to their families or to the community at large. Fear that they may not stand an equal chance with able-bodied men is very common. They are appreciative of acts of kindness if not overdone. Those who are badly disfigured are especially concerned by the doubt whether they are lovable by women any longer, and acknowledge gratefully any evidence that this is still the case. Fear that they receive sympathy or pity, which they loathe, rather than true affection, which they want, is hard to dispel. Their feelings of inferiority account for their frantic desire to conceal their disability and, if it makes them dependent on other people, to assert their independence. Like any other minority uncertain of its social status, they clamour for their rights and are very sensitive to any real or imagined encroachments upon them. Since time immemorial evil-doers have repeatedly been depicted as disabled, freaks, or cripples. These writers obviously sensed that disablement mobilizes aggressiveness arising from envy and frustration. Owing to their ill-temper, disabled persons are often difficult to get on with.

Types of Emotional Reaction

1. *Resignation; Indifference.*—Arguing that it is no good crying over spilt milk, a severely disabled man may arrange his life according to the changed circumstances; or, if his intelligence is too low to grasp the full extent of his handicaps, he may be indifferent to what has happened. But more commonly a disablement causes an emotional disturbance which persists after the almost universal initial upset.

2. *Depression.*—Mourning is the normal emotional reaction to any bereavement; and just as the mourner either gives way to his feelings or conceals them in front of others, so the disabled man, inevitably mourning his losses, either is frankly depressed or hides his grief behind a wall of psychological defences. In some men grief over loss persists. In a constant depressive mood, or in moody spells, they surrender to feelings of helplessness, despondency, a sense of unworthiness, and self-accusatory and self-condemnatory ideas. They shun crowds, social gatherings, and places of entertainment, but are equally afraid of the long hours of self-imposed loneliness. They want to have the constant companionship of an understanding friend who will "do" for them what they are unable to do for themselves, but who otherwise takes no notice of their disability and treats them as "normal" in all possible ways. In public they feel that everybody looks at them and passes remarks about them. A harmless remark may make them cry.

3. *Anxiety.*—Most disabled men realize that, in view of the present scarcity of man-power, their immediate future is not in danger. But the disabled ex-Service man hankers for permanent security and wants to be employed on his merits and not out of sympathy. He is afraid that after the war he will be unable to compete in a labour market flooded by returned able-bodied soldiers and highly skilled workers released from the war industries. In addition to justified concern there are commonly elements of unreasonable fears, specific in object, abnormal in quality, and related to their depressive states. Such disabled men minimize their working capacity and magnify the obstacles ahead. They paint a gloomy picture of the future and visualize themselves, whatever their real prospects, as starving, begging, or grinding a barrel-organ at the street corner. A disabling injury shatters a man's belief in his inviolability. Most disabled men are therefore more than usually afraid of further injury to themselves; in some this fear assumes quite grotesque proportions.

4. *Resentment.*—A prominent feature in a group of disabled men is resentment, either with or without depression. These men project resentment at their own fate on their current difficulties, suspecting ill will where none exists. Some men of this type ruin their occupational security and marital happiness by their uncontrollable temper, while others, like plaintive, peevish, and sulky children, refuse to make any real effort to earn their living. Others find a scapegoat for their resentment by directing it against the Government, various Ministries, the Army, or the community at large.

5. *Defiance.*—As in the air-raid slogans—"We can take it" and "Business as usual"—some disabled men adopt a defiant attitude towards their disability. Men of this type are usually good soldiers. On the battlefield, though severely wounded, they carry on until they collapse; and in hospital they wish to get up before they are fit. If a change of occupation is required they settle down to their training with great seriousness and determination; sometimes defiantly they choose occupations for which, in view of their disability, they are ill suited. The necessity of providing for their dependants is constantly on their minds. Their conduct calls for admiration, on which some of them thrive; others resent it and only want to be regarded as "normal." Some realize that they are constantly fighting against feelings of depression; others deny it, stating that their only concern is to get on with the job. If their façade cracks under the pressure of adversity they are apt to break down.

6. *Cheerfulness.*—Some disabled men appear to be in high spirits. These men are well liked by the staff in hospital, where, laughing and joking over their disability, they keep up morale in the wards. If any chance of recovery is left, and even if there is none, they are firmly convinced that in the end all will be well. They profess to be in no doubt that jobs by the score are waiting for them once they have been discharged. Strange though it may seem, this kind of attitude is particularly common in the early phases of the severely disabled, who by this process of make-believe deceive themselves concerning the incapacitating effect of their disability. Useful as it is at the beginning, this mechanism of self-deception, if continued, not infrequently prompts them in the choice of unsuitable occupations and seriously impedes their successful training. A certain number of men no doubt realize that they are acting, and while they are trying to "laugh it off" inwardly feel differently. Genuine satisfaction over loss was expressed by a small number of men, who had in this way expiated a deep sense of guilt.

B. Specific Differences

Quantitative Differences

A glance at Table I shows that the severity of the emotional reaction to disablement depends only to a limited extent on the severity of the actual handicaps. Compared with other disabilities a depressive mood prevails most often in the blinded. But for the excellent care of the blinded at St. Dunstan's this would more frequently be the case. For the same reason, despite the severity of their disability the blinded are less resentful at their disablement than other classes of the disabled.

Table I

	Depression %	Resentment %	Anxiety %	Defiance %	Cheerfulness %	Resignation; Indifference %	Grossly Abnormal %
Loss of one eye	23	20	34	8	1	14	—
Leg amputation	11	18	6	24	27	12	2
Arm amputation	24	27	6	20	16	7	—
Blindness ..	30	11	—	24	12	8	15

Generally, arm amputees are more severely affected emotionally than leg amputees. The high incidence of morbid anxiety, of depressive and resentful reactions, in those who have lost one eye is remarkable. Loss of an eye is not a disability which calls for much defiance to overcome it. Once again the effectiveness of the handling of the blinded at St. Dunstan's is underlined by the high frequency of defiant and cheerful reactions in them. As might be expected, in the disabilities considered, leg amputees and monocular personnel constitute the highest percentage of those who resigned themselves to their loss, while grossly abnormal emotional reactions occurred most often in the totally blinded.

Qualitative Differences: (*a*) Loss of Vision in One Eye

Soldiers who lose one eye are usually retained in the Army. This gives them temporary security, which is, however, insufficient to prevent a certain number of them from worrying unduly about their own future and that of their dependants. Another common source of anxiety is dread of injury to the remaining good eye. Fear of blindness in the one-eyed accounts for most of their complaints, such as headaches, eye-strain, blurring of sight, photophobia, and night-blindness. There is no physiological basis for these complaints, which are often very much dramatized. Their danger-consciousness rather than their actual handicap impairs the military and civilian working efficiency of many one-eyed men. Typical of this group is a monocular regimental policeman who did not dare to go out in the daytime because of the bright sunshine or at night because he might bump into something, and who hesitated to arrest an offender because the man might struggle and injure the good eye.

Loss of an eye is usually easily detectable. People are apt to comment on the one-eyed man's defect, and if his socket is still discharging he may be repugnant to other people. In view of the intact vision in the remaining eye, monocular persons, in contrast to the blind, are painfully aware of the social effect of their disability. This causes mental suffering in a fair number of them; some are frankly depressed, others are resentful about it. Both mental attitudes may result in social withdrawal.

Under Service conditions loss of an eye entails lowering of medical category and not infrequently of military status. For combatant soldiers especially this is an additional strain, which either aggravates their depressive mood or reinforces their resentment at their disablement.

(*b*) Blindness

Compared with other war-disabled, the totally blinded are worse off because of the severity of their handicaps and better off because of the care they receive at St. Dunstan's. Blinded men, with few exceptions, have to change their occupations, and they are incapable of taking full part in sport. Visual pleasures can only be conveyed to them through the medium of an escort. They learn to move about in familiar surroundings, but need to be escorted in strange districts and across roads on which there is much traffic. Their reliance on sighted people—for instance, in reading their incoming letters—deprives them of a good deal of their privacy.

Their restrictions and their unavoidable dependence on sighted people are naturally strongly felt by many of them. Some of them are unable to shake off their initial despondency and are subject to depressive moods, which, it is true, decrease in intensity and frequency as time goes on. Many blind men need company or must be busy to keep their spirits up; if left alone or idle their mind goes back to what is now denied to them.

To ward off depressive introspection or retrospection blind men make use of two psychological defence measures. They either admit their handicaps but make a determined effort to master them, or they deny their existence, make light of them, or profess to be little concerned about them. In the former case these men plunge into their new training to the exclusion of everything else; in the latter they display a false jocularity often coupled with a self-deceiving optimism regarding recovery of their vision. Men with empty sockets may cheerfully accept their misfortune, firmly convinced that their sight will come back.

Thanks to St. Dunstan's, fear about the future, resentment, and bitterness are less common in the blinded than in other groups of the severely disabled. But the general belief that blind persons are meek is basically erroneous. As they are unable to see what delays their attendants, their very disability makes for impatience. Frustrated in their major aims and in many small ways, they are apt to be ill-tempered; slips on the part of sighted people, whom they envy, especially rouse their temper. But their defencelessness, their dependence on sighted people, and their need for affection compel them to check their aggressiveness, which shows itself very clearly in their sarcastic wit, their dreams, and their fantasies.

Misinterpretation of imperfectly understood happenings, allied to feelings of inferiority, makes the blinded suspicious, and doubt as to whether they are still lovable, jealous. Their jealousy and suspicion may assume grossly pathological proportions, and may then, in combination with dreaminess and solitariness, become symptoms of a clinical picture which to all intents and purposes conforms to Kraepelin's paraphrenia. Two men in the series of blind men examined developed a typical schizophrenia subsequent to their blindness. A hysterical overlay is also common in the blinded.

(*c*) Amputation

The situation of the amputee differs from that of the two other groups of disabled in two ways: (1) he can be provided with an artificial substitute which is of functional value; (2) he re-enters the labour market at an early date without the backing of an organization such as St. Dunstan's.

1. The functional efficiency of artificial legs is superior to that of artificial arms. About a half of the arm amputees studied could not or would not make use of their artificial arms. Minor limitations and complaints, such as aching of the sound leg after a day's strenuous work and difficulty in lifting weights and in kneeling, are fairly common in leg amputees. Generally speaking, the loss of a limb has a slowing-down effect.

2. In many cases the amputee is able to return to his previous job or, at least, to his previous trade. If not, to find a suitable job may constitute a major problem: many firms are apt to employ amputees in inferior jobs. Amputees, more than others, are conscious of their precarious work-position, and the possibility of stump relapses requiring hospital treatment is an ever-present worry.

During the early stages, before the provision of an artificial limb, the immediate effects of their disability are the men's main concern. During this period grief over loss or defensive ultra-cheerfulness usually prevails. A man on crutches is an object of pity, and the loss of an arm is, and remains, very conspicuous. Cheerfulness may be merely protective against depressive thought and feeling, and is then based on combatant pride and exultation over survival; or it may be quite genuine in a few isolated instances of unwilling soldiers who were glad to be "out of it" ("Blighty reaction"). Right from the beginning a certain number of men, conscious of their responsibilities and obligations, were firmly determined to make a fresh start and to master their disability.

With provision of artificial limbs the struggle for existence begins. By this time early grief over loss and false cheerfulness have receded. Instead, as a result of the impact with social and occupational difficulties, defiant and resentful attitudes grow in frequency (Table II). Until then the wounded soldier had been nursed and fêted; now he begins to realize that society still makes demands upon him. Some men are spurred on by these demands, whereas others only feel bitter about them. Bitterness originally arising from their disablement is fed by their actual handicaps—e.g., stump relapses or deficient functional value of the artificial limb—or by unsuitable or uncongenial employment. Men of the defiant type overcome and may even thrive on the obstacles placed in their way. Their impressive success is related to their previous personality, and can by no means be expected from every amputee.

Table II

Artificial Limb	Depression %	Resentment %	Anxiety %	Defiance %	Cheerfulness %	Resignation; Indifference %	Grossly Abnormal %
Prior to provision	19	11	7	14	29	17	3
After provision	12	28	4	27	21	7	1

II. SOCIAL SITUATION

Success and failure of the disabled man's social readaptation on return to civilian life depend on his attitude to the community and on the attitude of the community to him. An important factor is undoubtedly his attachment to or detachment from the Army. If the "Blighty" effect is pronounced his readaptation is easy, but if his identification with and integration within the Army had been complete, detachment becomes difficult. He then decries the separation from his comrades, whom he envies because they are able to carry on the fight, and, though he may not recognize it, he feels guilty over being "out of it." Averse to mixing with civilians, whom he tends to despise, he tries to surround himself with serving men, thus painfully reminding himself of what he has lost for good. Some men take refuge in the company of others who share their fate; extreme cases of depression turn away from the community altogether, whereas men of the resentful type become troublesome through their impatience, irritability, and disgruntled mood. Men who have lost their one and only prop by their discharge from the Army start on a roving aimless existence.

The community, on the other hand, receives the returned disabled soldier with a mixture of curiosity, praise, pity, and horror. People want to know how it happened, and express disappointment if it was "only" due to a Service accident at home. They acknowledge the hardships and dangers to which he had been exposed while they lived in relative comfort and comparative safety. At the same time he demonstrates to them what is inevitable in warfare, what is even highly desirable if done to the enemy but what they do not want to happen to or to see in those who are near and dear to them. To make up for this they therefore celebrate the return of the disabled soldier and shower gifts upon him. They put the flags out in his village, arrange reunion parties, while perfect strangers stand him free drinks in the local and passers-by slip shilling-pieces into his pockets. Inadvertently, admiration for the returned hero has passed into charity for the war cripple. Both pity and excessive praise are ill received by disabled soldiers, who sense what they call insincerity. They neither feel like nor wish to be treated as returned heroes. They ask for recognition of their services but not for noisy praise. For the same reason most disabled men do not want and even reject special privileges, but gratefully accept unobtrusive consideration and allowances for the specific requirements of their disability.

The social situation of the three disabilities under consideration varies in some respects. Blindness has primarily an awe-inspiring effect which makes many people reluctant to visit the recently blinded, to approach him, or even to talk to him. If the barrier is broken their talk is often unnatural because they are afraid of saying the wrong thing. Many blind persons complain that their presence has a dampening effect on other people's hilarity. Fear of blindness is much more common than that of any other mutilation. Hence pity and charity are much more frequently and more liberally forthcoming towards the blinded than towards other disabled. By overdoing it people may do more harm than good. Blinded persons resent both sloppy pitying and patronizing interference by sighted people, well-meaning in their intentions but ill informed about the real handicaps of the blind. Amputees need less assistance than the blind and therefore resent it all the more. Well fitted with an artificial limb, they like to think that their defect is not noticeable, and are disappointed if this is not always the case. Loss of an eye does not call for much sympathy. Monocular persons meet with a certain amount of social prejudice and, as the derogatory usage of the word denotes, the one-eyed may be subjected to some harmless badinage.

What is true for the large community is equally true for the small family circle. To see her son maimed is grievous for every mother, and elicits in her a response of loving care. For her he is her hurt child, and she treats him as such. Conversely, the disabled man on return home is in need of and appreciates acts of kindness and consideration, but after a while he gets tired of being mollycoddled and recovers his sense of independence. Many a loving mother or wife, however, keeps on fussing over him; they open doors for him which he could open, rush up and down the stairs which present little difficulty to him, and show great concern if he ventures to go out alone.

Women in general approach disabled men in three different ways. Cases of mild or moderate disablement may become a centre of attraction for a certain type of woman. A state of helplessness appeals to the maternal feelings of others, and they stick loyally to him however severely he is disabled. If he is very badly maimed some women will turn away from him: self-interest and the horrifying effect of the disability prevail.

III. OCCUPATIONAL SITUATION

Success of resettlement of disabled men depends on their actual handicaps, the functional efficiency of artificial substitutes (in amputees), the previous personality of the men, their emotional reaction to disablement, the efforts of the authorities concerned with their placement, the attitude of their employers, and the suitability of their employment.

So far as the men are concerned, factors which make for good working efficiency are: (1) absence of residual complaints; (2) a previous conscientious personality; (3) a defiant attitude towards disability; (4) anxiety about the future; (5) disinclination to relax (in the blinded). Men of the defiant type, all out to attain equality with able-bodied workers, will do well even against heavy odds, while men anxious about their present or future security may content themselves with inferior jobs so long as they make a decent living. Many blind men dread their leisure hours, when they become dispirited and tend to brood. They are therefore eager to work extra hours, but do not stand up well to industrial slackness.

Factors which imperil successful resettlement or impair the disabled men's working efficiency are: (1) the presence of residual complaints—e.g., stump relapses in amputees; (2) domestic trouble brought on by disablement; (3) dependent trends, sometimes allied with hysterical features; (4) depression; (5) resentment; (6) over-defiance; (7) self-deceiving over-cheerfulness; (8) intelligence too high or too low for the job obtained.

Men who had previously been work-shy can obviously not be expected to be first-rate workers simply because they are disabled. They usually make the most of their disability and complain that excessive demands are made on them. Grief over loss, if persisting, paralyses a man's initiative and, like resentment, prevents him from making a whole-hearted effort at work. Both resentful and depressed individuals withdraw socially and are, for this reason alone, ill suited to join a working community. Suppression of the disabling effect in self-deceiving over-cheerful individuals, and desire to attain the unattainable in over-defiant individuals, may be operative in the choice of unsuitable occupations. Both attitudes may lead not only to disappointment but in some instances to a complete breakdown.

Adverse outside factors beyond the control of the disabled men are: (1) erroneous vocational guidance; (2) employment in unsuitable jobs, especially inferior jobs; and (3) unsatisfactory management at their place of employment. With a few exceptions, all the amputees were in employment at the time of examination. A high proportion of men who in peacetime had been skilled workers changed over to clerical occupations after their disablement. Their tendency to give up their skilled jobs was generally not warranted by the type of their disability. Roughly half of the leg amputees were in occupations which required prolonged standing, such as fitters, welders, and assemblers; or walking and car-driving—e.g., factory inspectors, salesmen, roundsmen; or even heavy lifting—e.g., stokers and railway porters. About a third of the arm amputees were in occupations which required great manual skill, such as fitters and welders. About two-thirds of the amputees were satisfied with their employment. Those who were dissatisfied complained that their occupations were too strenuous, were only temporary and must come to an end after the war, were too monotonous, or did not give them enough scope or a chance of promotion.

The majority of the blinded who were examined were happy at their work; a small minority stated that their jobs were boring in view of their intellectual capacities and aspirations. The war-blinded studied were employed on progress chasing, splicing, viewing, fuel-tank pressure testing, building up air intakes, identifying, assembling, machine-operating, and deburring; one was a tobacconist, and another—a work-shy hysterical individual—a sweeper. The progress chaser and the sweeper were semi-sighted. Monocular men could not be followed up into civilian life.

Summary

405 war-disabled persons were psychiatrically examined (200 amputees, 103 blinded, and 102 who had lost vision in one eye).

Their emotional, social, and occupational difficulties are discussed.

The physical handicaps of monocular persons are negligible. Physical handicaps apart, the difficulties are predominantly emotional in the one-eyed, social in the blinded, and occupational in the limbless.

Rehabilitation of the war-disabled can only be successful if due regard is given to their emotional, social, occupational, and financial situations.

My thanks are due to the Army authorities for permission to publish this article.

OXALURIA IN BRITISH TROOPS IN INDIA

BY

J. M. BLACK, M.B., F.R.C.S.Ed.

Lieut.-Col., R.A.M.C.; Officer in Charge of a Surgical Division, B.G.H.; Honorary Surgeon, Dunfermline and West Fife Hospital

The most interesting feature emerging from a survey of urological cases admitted to the surgical division of a British general hospital was the frequency of oxaluria as a cause of symptoms. The cases investigated were those of men from a British division in training in India and admitted to hospital during the 12 months Jan. to Dec., 1943.

Relative Frequency of Urological Conditions

Of 1,000 operations carried out during Jan. to Dec., 1943, 68 were for urological conditions and only 28 for acute abdominal conditions. Table I shows the total number of urological cases investigated and treated during that period.

Table I.—*Summary of Urological Cases (77)*

Condition	No. of Cases
Oxaluria	43
Ureteric calculus	16
Renal calculus	7
Hydronephrosis	5
Sulphapyridine kidney	4
Tumour of kidney	1
Bladder diverticulum	1

Of the 77 cases investigated no fewer than 43 (55%) were found to be suffering from oxaluria. Oxaluria was not diagnosed until a full investigation—viz., cytological and bacteriological examination of the urine, cystoscopy, and intravenous or retrograde pyelography—had been carried out.

Clinically oxaluria manifested itself in one of the three different ways shown in Table II.

Table II.—*Oxaluria: Symptoms (43 Cases)*

Symptoms	No. of Cases
Oxaluria with renal colic	20
Oxaluria with haematuria	15
Oxaluria with epididymitis and cystitis	8

A short case history of each type best illustrates the clinical symptoms and signs.

Oxaluria with Renal Colic

Pte. H., aged 23, was playing cards after dinner when he was seized with violent pain in the right iliac fossa. He felt sick but did not vomit, and there were no accompanying urinary symptoms. Twenty minutes after the onset of symptoms he was admitted to hospital with a diagnosis of "? perforation." He had had no previous symptoms.

On examination he was restless and pale, and was vomiting. Tenderness, rigidity, and hyperaesthesia were present in the right iliac region. No abnormality per rectum. After admission he passed 4 oz. of concentrated urine, the laboratory report on which read: "A few R.B.C. and many calcium oxalate crystals." Cystoscopy, carried out on the following day, revealed a trigonitis with pouting oedematous ureteric orifices. Cultures from the cystoscopic specimen of urine were sterile.

Retrograde and intravenous pyelograms showed a normal renal tract. The man was discharged to his unit, symptom-free, after nine days in hospital, and reported to the surgical out-patient department for three weeks.

Of the 20 cases of oxaluria with renal colic only five had urinary symptoms—frequency or strangury. Two had suffered from recent previous attacks and two had lately had amoebic dysentery. (A relationship between oxaluria and amoebic dysentery has been emphasized by Manson-Bahr.)

The average duration of symptoms before admission was 19 hours and the average stay in hospital 17 days. During this time eight of the patients were cystoscoped and retrograde pyelography was done, and in the remaining 12 intravenous pyelography was carried out; all were negative for calculus. The influence of diet and the importance of fluid intake were stressed to each man on his discharge from hospital, and there were no recurrences requiring readmission.

Oxaluria with Haematuria

Pte. G., aged 33, was on a route march on April 5, 1943, and at 10.30 a.m. halted to pass urine. He noticed his urine was "slow in coming" and was like blood. He carried on till afternoon, and again passed urine "like blood"; he reported to the R.M.O. and was sent to hospital.

There was no previous history of symptoms of calculus. On close questioning, he had been drinking a "lot of strong tea" before starting on the route march. For the past two months he had passed urine only twice in the 24 hours.

Physical examination revealed nothing abnormal. Urine passed after admission to the ward was deeply stained with bright-red blood. Cystoscopy at 5 p.m. the same day showed intense congestion of the trigone and blood-stained urine spurting from both orifices. White crystalline material (oxalate crystals) was embedded in the bladder mucosa in large amount and was floating in the fluid medium. The bladder was washed out with normal saline. A catheter specimen, taken before cystoscopy, showed: "Albumin: a heavy cloud. Deposit: numerous R.B.C.; no pus cells; no organisms. Many Ca oxalate crystals. Cultures sterile."

He was put on forced fluid intake, and in 24 hours (April 6) a laboratory examination of urine showed: "No albumin; deposit *nil.*" Cystoscopy on April 13 showed a healthy bladder mucosa; no evidence of crystals or blood-clot; both ureteric orifices secreting normal urine. Examination of urine revealed: "Albumin *nil*; no R.B.C.; a few Ca oxalate crystals; occasional epithelial cells only; culture sterile." Radiographs taken after intravenous uroselectan showed "a normal renal tract."

On April 26 the patient was discharged to duty; no recurrence has been reported.

The investigation of the 15 cases of oxaluria with haematuria is summarized in Table III.

Table III.—*Haematuria with Oxaluria: Symptoms*

Symptoms	No. of Cases	Average Duration of Symptoms before Admission (Hours)	No. of Previous Attacks	Average Stay in Hospital (Days)
Painless haematuria	4	21	Nil	24
Haematuria with dysuria	4	54	3	26
Haematuria with renal or ureteric pain	7	58	6	19
Average		44		23

The urine in all 15 cases contained red cells and calcium oxalate crystals, and culture from the urine was sterile. Cystoscopy showed a trigonitis in all cases, and in six of them small brownish particles (old blood-clot) were present in the bladder. Intravenous pyelograms or retrograde pyelograms, done in all 15 cases, demonstrated no abnormality.

Oxaluria with Epididymitis

There were eight cases of this condition, which in my opinion is a distinct entity.

Typical Case History.—Pte. S., aged 21. Five days before admission he had frequency and burning, and after micturition some pain referred to the point of the penis. The next day he felt pain in the left testis and groin, and the left testis was swollen. There was no history of injury or V.D. infection, or exposure to such infection. On examination there was no urethral discharge; the left epididymis was swollen, soft, and tender, with maximum tenderness at the lower pole, and also tenderness along the left vas deferens. Per rectum there was definite tenderness but no thickening of the vesicles. Urethral smear and Kahn test were negative. Urine examination on the day of admission revealed "a few R.B.C. and epithelial cells; oxalate crystals in large numbers; cultures sterile." Cystoscopy on day of admission: Marked trigonitis; crystals of ? oxalate embedded in bladder mucosa. The bladder was washed out with normal saline. I.V.P. and cystogram showed normal renal tract. After three weeks' treatment with forced fluid intake and rest in bed the epididymitis cleared up completely.

With regard to *symptoms*, five of the eight cases had some dysuria before the onset of pain and swelling of the epididymis, which was affected on the right side in six cases and on the left in the other two. Two men gave a history of mild trauma to the affected organ; in two the condition developed after lifting heavy weights, and in the other two P.T. was the alleged cause.

Clinical examination revealed no systemic upset, the temperature and pulse rate being normal. The epididymis in all cases was swollen, soft, and tender, and the maximum intensity of signs was at the lower pole. There was also definite tenderness of the vesicles on rectal examination.

The urine in all cases showed calcium oxalate crystals, and cultures were sterile and there were no pus cells in the deposit. Both urethral smear and Kahn test, done in five cases, were negative.

The average duration of symptoms before admission was three days and the average stay in hospital 17 days. The short duration of the symptoms, the absence of systemic upset, and the rapidity of resolution, together with the absence of any infection of the urinary tract, make me believe that the condition is one of irritative epididymitis due to oxaluria and direct spread down the vas—the "straining" at P.T., etc., possibly causing this back-flow.

Oxaluria in Cases of Renal and Ureteric Calculi

In two of the 16 cases of ureteric calculi in this series oxalate rystals were present in the urine, and in the calculi recovered alcium oxalate was the main constituent. In three of the even cases of renal calculus oxalate crystals were found in the rine, and oxaluria was present in two of the five cases of ydronephrosis investigated.

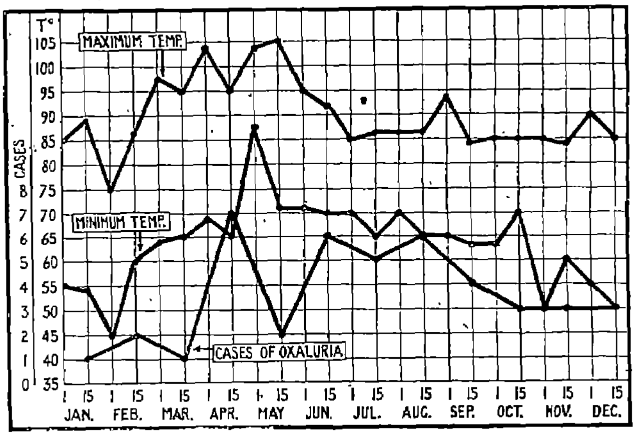
Discussion on Oxaluria

It is well known that oxalate crystals can be passed in the rine for years without any tendency to calculus formation. xalates may be deposited at any reaction. Most commonly hey are deposited after the urine has been passed and cooled. ut they may be present *in vivo* in suspension in the urine nd cause irritation, and occasionally even slight haematuria Harrison, 1939). Microscopically they may be in the octohedral r envelope form, in the dumbbell form, or in the biscuit form.

To avoid oxaluria, sorrel, rhubarb, and asparagus—which ontain more than 2 g. of oxalic acid per kilogramme—and xcess of chocolate should be eliminated from the diet. The eneral opinion is that it is useless to try to control oxaluria by educing the calcium intake or by increasing the magnesium–alcium ratio, and that neither acid nor alkaline therapy is dicated in cases of calcium oxaluria.

The frequency of oxaluria in the present series can be scribed to: (1) the climate—causing loss of body fluid by weating and concentration of the urine; (2) the diet—adequate fluid intake and the presence of oxalate-forming food in the diet (tomatoes, strong tea). Neville in 1935 found that oxaluria was apt to occur in vitamin B deficiency, but in this series there was no clinical evidence of such deficiency. The association of amoebic dysentery with oxaluria noted by Manson-Bahr was observed in only two of our cases. The excessive formation of vitamin D by sunlight is said to be connected with tropical lithiasis.

The seasonal occurrence of oxaluria is illustrated by the fact that 30 cases were admitted to hospital during April to Sept., 1943 (the hottest part of the year), and only 13 cases during the periods Jan.–March and Oct.–Dec., 1943—times when the weather is definitely cooler (see Graph).



Graph showing minimum and maximum temperatures for 1943 and occurrence of oxaluria.

It would appear that the oxaluria resulting from the two constant factors often causes haematuria, which leaves the binding material in the form of blood protein. Oxaluria continues (demonstrated by the finding of oxalates in the urine in three of the cases of renal calculus and in two of ureteric calculus) and stone formation results. Diagrammatically its formation can be shown thus:

(1) Diet (2) Inadequate fluid intake
\ /
OXALURIA
/ \
Haematuria Deposit of oxalate crystals
| |
Fibrin Retention of fragments of crystals
\ /
Calculus

All the stones recovered and examined consisted of a mixture of calcium oxalate and calcium phosphate. There was no pure oxalate stone. *Treatment* thus resolves itself into the prevention of oxaluria by: (1) Elimination of oxalate-forming foods from the diet. (2) Ensuring a fluid intake of adequate amount to prevent concentration of the urine. (3) In hospital cases, especially those requiring immobilization, a fluid intake of at least eight pints a day and ammonium chloride to prevent phosphatic deposit. The *duration of incapacity* in oxaluria and ureteric and renal calculus is shown in Table IV.

TABLE IV

No. of Cases	Condition	Average Stay in Hospital (Days)
43	Oxaluria	19
16	Ureteric calculus	44
7	Renal calculus	56

Conclusions

The presence of oxaluria, and the haematuria accompanying it, accounted for the majority of urological cases requiring hospital treatment. The combination of haematuria and oxaluria is the direct precursor of calculus formation. Infection does not seem to be a factor.

Adequate fluid intake and the avoidance of oxalate-containing foods are the two measures most likely to prevent oxaluria and the complications resulting from it.

Summary

Of 77 urological cases occurring in men of a British division in India and admitted to a British general hospital during Jan. to Dec., 1943, 43 (55%) had oxaluria. Oxaluria was also present in five cases of renal and ureteric calculus reviewed in this series, and in two cases of hydronephrosis. Of the cases of oxaluria 30 occurred in the period April–Sept., 1943.

Eight cases of epididymitis considered to be due to oxaluria were investigated.

My thanks are due to Major J. L. Dales, R.A.M.C., who carried out the laboratory examinations; to Major N. A. Lawler, R.A.M.C., who was responsible for the radiology in the cases reported; and to Col. Frank Cook, officer commanding 60 B.G.H., for permission to publish this paper.

INTRAVENOUS ANAESTHESIA WITH PENTOTHAL SODIUM

BY

BARNET SOLOMONS, M.B., B.S.
Major, R.A.M.C.; Specialist Anaesthetist to a Neurosurgical Unit in a Tropical Climate

This is a short survey of points arising out of the use of pentothal sodium since its introduction, including its administration to more than 700 acute battle casualties in a tropical area.

Most of the soluble hexobarbitones are powerful hypnotics only, and are unsuitable for continuous intravenous anaesthesia. Pentothal sodium has been of more general use in acute war surgery here than any other anaesthetic drug. The contraindications to the use of pentothal become less and less in proportion to the accumulated experience of the anaesthetist. The barbiturates are exciters of the parasympathetic nervous system. After a possible early dilatation the pupil tends to remain small, the only reliable third-stage eye sign being its central position. Hiccup and irritative spasmodic cough are not uncommon. The pharyngeal and laryngeal reflexes may remain active, and may be evoked by stimuli arising about the mouth, jaw, or pharynx, or by pain stimulus from a distance. These reflex disturbances are much more common in exhausted battle casualties, and especially in cases of injury involving the neck and thorax.

Continuous intravenous anaesthesia has been avoided in penetrating injuries of the upper abdomen and in severe wounds of the jaw or neck. The latter may be associated with oedema, or there may be mechanical obstruction by displaced tissues or blood, directly interfering with the airway.

Method

The anaesthetist should have two hands free to supervise or carry out any necessary measures of resuscitation during operation. To this end many suggestions have been published already, but the simplest method seems to be that of a rubber tube and glass cannula interposed between syringe and needle. There are obvious disadvantages in any fastening of the syringe to the patient's arm. A syringe-holding clamp has been devised (Fig. 1) which fits firmly to any arm-board. This has been used for nearly three years, and proved a definite aid. The actual syringe-holder consists of a trough which is adjustable to hold firmly any syringe from 10-c.cm. to 50-c.cm. capacity. A swivel allows of ready adjustment of the rubber tube to the line of the vein, so that the needle lies comfortably, and fixation by adhesive is seldom necessary. A three-way tap is useful in dealing with numbers of cases consecutively. One arm of the tap is connected to a pentothal reservoir, one to the syringe, and on to the third fit the tube and cannula. The syringe is easily refilled, and remains fixed and sterile. Between cases only the tube to the patient needs removal and sterilization. For success with the method good syringes, preferably all-glass, are essential, as most metal-and-glass types allow of back leakage of the solution round the piston. The tap is turned off (*a*) when piercing the vein; (*b*) in the intervals between the injection of solution; and (*c*) when refilling the syringe with solution. There is less possibility of blood clotting in the needle if a 17- to 19-gauge needle is used, and also if a minute quantity of solution is injected at frequent intervals to prevent stagnation of blood in the needle. In head operations or when both arms are involved the anaesthetist must work at the ankle, where in many cases, even after compression, veins are not easily visible or palpable. In such cases anaesthesia is induced by injection of a small hypnotic dose into any accessible vein, and, if necessary, the airway is controlled by intubation. Vasodilatation then occurs, and there will be present at the ankle, or on the dorsum of the foot, a network of prominent veins which allow of easy puncture even when no vessels were apparent before induction. Anaesthesia can be carried on at the ankle, combined, if necessary, with transfusion of any suitable fluid, without the necessity for cutting down on a vein.

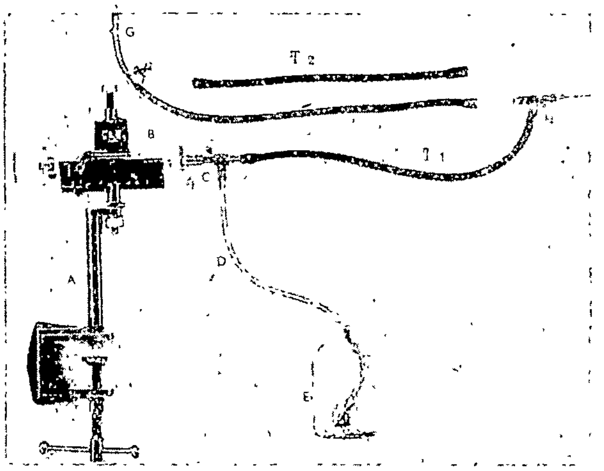

Fig. 1.—Apparatus connected as for combined anaesthesia and transfusion. A: Clamp to screw on to any arm-board holding syringe B. C: 3-way tap. D.: Weighted tube to pentothal reservoir E. G: Tubing from transfusion bottle plugged via glass cannula into Y-connexion H on which fits needle. T1: Tube to needle. T2: Tube and cannula to fit needle for anaesthesia without transfusion.

Owing to the increased sensitivity of the pharyngeal and laryngeal reflexes, any artificial airway, either pharyngeal o nasal, is very likely to set up a laryngeal spasm. This may be most troublesome and sometimes difficult to abolish completely Spasm may occur or persist at a plane of anaesthesia deepe than that required for the operation itself. Spasm and coughing are not always evidences of light anaesthesia when using barbiturates. To deal with spasm of any severity access to the tongue and posterior pharynx must be easy, as most case will respond to the hooking forwards of the base of the tongu with a finger or tongue forceps. The latter can be used unopened as a curved spatula. To allow of easy access a prop has been devised (Fig. 2), which is shaped to fit comfortabl between the teeth before induction, without causing gagging o discomfort.

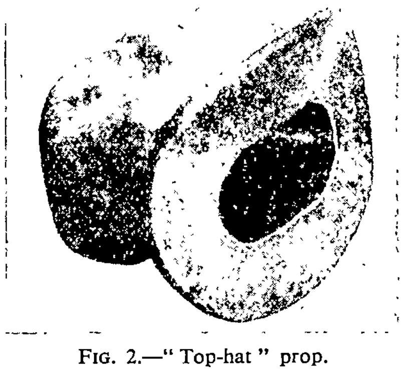

Fig. 2.—" Top-hat " prop.

The head should be placed in a position approaching that o normal comfortable sleep. With the small prop in the mou the head is turned gently to one side immediately sleep is induced, and the chin is supported; the tongue does not tend to fall back, and the breathing, which formerly may have been oral, now becomes quiet and entirely nasal in most cases. The prop itself is in no sense an airway, but it has a central oval aperture which will admit any of the flat-type rubber or metal pharyngeal airways. As explained before, the introduction of any such airway is inadvisable. If an airway is used it should be greased with a stiff ointment containing one of the surface-acting local analgesics. A thick pad of sorbo rubber introduced between the chin and the clavicle is very suitable as a chin support.

Results

Pentothal gives good results in 2½% solution. In this strength accidental paravenous injection has not caused irritation to the tissues. Only once has thrombosis occurred with this solution. In this patient thrombosis was at the bend of the elbow, the injection having been given at the wrist. Solutions keep well, and no clinical differences have been noted when using solutions 48 hours old. As a test, a 2½% solution in ordinary tap-water in a non-sterile tube was kept open on the laboratory bench for 72 hours. Subsequent cultures were sterile. To part of this same solution were added two strains of staphylococci and one of streptococci from routine laboratory specimens. No growth was obtained after culture for 48 hours.

Respiratory depression is lessened and all-round improvement in results obtained by the use of some form of gaseous inhalation in combination with intravenous pentothal. In most of the cases oxygen alone or gas and oxygen have been used. Cyclopropane was available late in the series. The administration of a gas–oxygen mixture facilitates maintenance of anaesthesia, aids relaxation, and lessens the total amount of pentothal necessary. Enough oxygen must be used to avoid cyanosis. By this method the retardation in rate and the shallowness of respiration commonly seen in anaesthesia with pentothal alone are avoided. Early spasm, if slight, can be abolished by introduction of carbon dioxide or by an increase in the pressure of the inhaled gases. In a few cases mild spasm or irritative cough may persist despite these measures. This is of small significance in operations on the limbs, and the anaesthesia should not be deepened unless the symptoms interfere with the surgeon, provided always that there is no evidence of lack of oxygenation of the patient.

Adequate premedication with morphine 1/8 to 1/4 gr., combined with scopolamine 1/150 to 1/100 gr. or atropine 1/100 to 1/75 gr., decreases the tendency to spasm and also the total dosage of pentothal required. A warning is essential in acute war surgery—at least in this theatre of war. From the point of view of the anaesthetist, the battle casualty usually arrives in the operating room over-morphinized. In most cases this appears to be due to somewhat lavish use of morphine, but in the debilitated state of many severe casualties even moderate morphine dosage may have a profound effect. It has been found wiser to omit any morphine pre-operatively unless the patient has been under local observation for some hours. A very small pupil is the commonest eye sign in battle casualties reaching operation, and the size does not alter throughout the anaesthesia with pentothal.

In many cases deep anaesthesia is unnecessary. In the toilet of most wounds, using the combined method, 0.3 to 0.75 g. is sufficient. In the major surgery of multiple compound fractures and in amputations it has not been necessary to exceed a dose of 1.5 g. Three disarticulations at the hip for gas gangrene—one of 70 minutes' duration—were carried out with a dosage of 0.75 g. each; there were no untoward symptoms, and all recovered well.

In a sudden military emergency with influx of wounded in large numbers, nursing facilities are strained and patients must return to bed from the operating theatre in a state in which they will need little or no immediate post-anaesthetic care. It has been found that most patients arouse in the theatre after provision of all anaesthesia necessary for their surgical needs. Vomiting has been conspicuously absent, and there has been no anxiety as to maintenance of free airway after return to the ward. Most of the men can take fluid and nourishment soon after their return to bed. They are encouraged to drink water in plenty up to 20 minutes before operation.

Sulphonamides have not been regarded as a contraindication to the use of pentothal. In the presence of sepsis and debility, caution and a much-decreased dosage of pentothal are essential. In this series no state of toxaemia or exhaustion has been an absolute bar to its use. It has not been employed in jaundiced patients. Although working in adverse tropical conditions and with patients debilitated by infective states, no case of delayed recovery of consciousness has been seen, despite the probability of latent liver deficiencies. Shock is not always a contra-indication to pentothal anaesthesia. Some casualties arrive pale, restless, and confused, and in these the intravenous injection of a few cubic centimetres of solution facilitates the introduction of plasma or other fluids and the use of a face-mask for inhalation of oxygen. These patients are kept only just asleep, and operation is not begun until recovery from shock is evident. If ether or high cyclopropane percentages are thought necessary a few cubic centimetres of pentothal are used merely as a single-dose pre-hypnotic, but ether is avoided wherever possible.

Conclusions

Pentothal in 2½% solution by the continuous method, preferably combined with inhalation of oxygen, gas–oxygen, or cyclopropane mixtures under slight pressure, is an anaesthetic of wide and satisfactory application in the treatment of acute battle casualties. A syringe-holding clamp, which facilitates administration, is described, also a mouth-prop. It is recommended that no artificial airway should be introduced, owing to the likelihood of cough and spasm. Intubation necessitating the maintenance of deeper anaesthesia was reserved for special indications.

I am indebted to Lieut.-Col. B. B. Hickey, R.A.M.C., for permission to publish this article, and to Dental Mechanic S. Dale of A.D. Corps for his advice in the design of the prop. Acknowledgment and thanks are due to the staff of the various Army workshops for their ready help in making the clamp and prop, and for prompt aid at all times in the construction and repair of anaesthetic apparatus.

The syringe, tap, and two-way adapter shown in Fig. 1 are made by Messrs. Becton Dickinson, but suitable apparatus is obtainable from Medical and Industrial Equipment Ltd., 12, New Cavendish Street, London, W.1.

TREATMENT OF SOFT WARTS WITH PODOPHYLLIN

BY

J. V. MACGREGOR, M.B., B.S.

Squad. Leader, R.A.F.V.R.; Specialist in Venereal Diseases at an R.A.F. Hospital

A treatment for condylomata acuminata which deserves to be widely known because of its simplicity and high rate of success has been described by Culp, Magid, and Kaplin (1944). From their results in a series of 100 cases treated with podophyllin they claim that:

> "(i) Podophyllin has been found to be unusually successful in producing prompt and complete disappearance of condylomata acuminata regardless of the size, number, location, or duration of the growths. . . . (ii) Podophyllin may be applied locally to the lesions as a 25% suspension in mineral oil or as a paste composed of the powdered drug and water. Anaesthesia is not required. (iii) Treatment is simple, the convalescence usually is painless, and the lesions disappear within two or three days after a single application, leaving no ulceration or scarring. Repeated applications of the drug may be necessary in a few instances. . . . (iv) The surrounding normal tissue is unaffected by the drug, but in isolated cases of extensive application under tight prepuces some balanitis may result. . . (v) The dramatic results obtained in this series of 100 cases and the simplicity of the treatment with podophyllin prompt us to recommend more widespread application of this type of therapy."

I have treated a series of 25 cases of condylomata acuminata and have confirmed the success achieved in the U.S.A. In addition one case of extensive warts of the face has responded equally well to podophyllin treatment.

Method

A suspension of podophyllin resin *B.P.* 25% in liquid paraffin *B.P.* was shaken and then applied liberally to the affected area, care being taken to ensure that the numerous crevices of a profuse crop of warts were penetrated and no attempt being made to confine the preparation to the lesion itself. The suspension must remain in contact with the warts for at least six to eight hours, and clothing must be prevented from absorbing it or rubbing it off. Hard crusts remaining from previous treatment must first be removed before a further application is made. The crusts can be softened with the podophyllin oil and left to soak in for a few minutes, after which they are easy to detach. After six to eight hours the oil should be washed off with soap and water, and the parts dried carefully, and kept dry with a powder such as pulv. zinci co. If this is not done inflammation may occur. An ordinary orange stick proved useful, the blunt end being used to apply the oil and the sharpened end to remove crusts and open up fissures between multiple warts to assist penetration.

Results

Twenty-five cases consisted of single or multiple condylomata acuminata of the penis or anus. Isolated warts shrivelled up and became yellow within 24 hours and dropped off in a few days, leaving no ulceration or scarring. Profuse growths usually required two or three applications. Treatment is painless. Normal tissue is substantially unaffected, in contrast to the action of the usual caustics. There is, however, a risk of inflammation, especially balanitis; but this may be obviated if precautions are taken as described.

One of these cases needs special mention. The man had been under treatment for penile warts for a year before I saw him. Treatment had consisted of (i) circumcision and cauterizing of warts with the galvano-cautery; (ii) application of a diathermy cautery three times; and (iii) two courses of small doses of *x* rays six and seven months previously. But after each treatment the warts recurred. On examination there was a most profuse cauliflower growth of warts covering and hiding the end of the penis. The warts were growing from the urinary meatus, glans penis, coronary sulcus, and along the line of the circumcision scar. Secondary infection had occurred, with the production of a profuse purulent offensive discharge. Compresses of flavine were used to combat the infection. Podophyllin in oil was applied to small areas at a time, so that in five weeks some 15 applications had been made. At the end of this period the penis was substantially normal except for scarring from previous treatment. One month later a few warts began to recur, but two applications in a week led to their complete disappearance.

After success in this case, with the meatal warts other cases of single meatal warts were treated successfully, without apparent ill effect on the mucous membrane of the urethra. In these cases the urine should be held for six to eight hours, so that the podophyllin is not washed away.

Another case is in a different category. It was a profuse eruption of warts of the face; chiefly in the beard area, maximal over the chin. The onset had been 18 months previously. In the interval treatment had been with (*a*) chemical caustics, (*b*) curetting, and (*c*) small doses of *x* rays. During four weeks 15 applications were made. Single warts dried up and fell off after one application, small bunches of warts responded to two applications, whereas the thickened and deformed skin of the chin required 10 applications.

Commentary

Single soft warts may be removed with success by several methods—e.g., caustics, curetting, ligature, and galvano- and diathermy cauteries. Most of these are painful. Multiple warts are more difficult to cure, and require either special skill or special apparatus. They present particular difficulty to *x*-ray therapy by reason of their situation and multiplicity, and also, in hairy regions, because of fear of epilation and permanent skin changes.

Podophyllin in oil is easy to obtain, simple in use, and successful in the more awkward kind of case—warts of the urinary meatus, and multiple warts of the penis, vulva, anus, and face.

To obtain success with podophyllin thorough and prolonged application is necessary. The case of warts of the face and two cases of warts of the anus had been treated by a colleague with podophyllin, on my recommendation, without success. Failure is thought to have been due to the podophyllin being absorbed into dry gauze dressings in the first instance and into underclothing in the second. Complete success was later obtained by ensuring that the oil remained in contact with the warts.

Summary

The results of treatment of warts with podophyllin reported by Culp, Magid, and Kaplin have been confirmed.

The preparation used was podophyllin resin *B.P.* 25% in liquid paraffin *B.P.* This is easy to obtain.

The treatment is simple and requires no special skill or apparatus, but the application should be thorough and prolonged.

It is suitable not only for single soft warts but also for more difficult cases, such as warts of the urinary meatus and multiple warts of the penis, vulva, and anus.

In addition multiple warts of the face disappeared under this treatment.

Two cases that had failed to respond to *x*-ray therapy were treated successfully.

The excellent results justify a wider acquaintance with podophyllin treatment and a trial in cases other than condylomata acuminata.

Medical Memoranda

Treatment of Chronic Otitis Media

Recruits are referred to specialists by Army medical boards if they have puzzling ear conditions. Most men have perforated tympanic membranes, the perforation usually being located centrally or antero-inferiorly, and so they are easy to cure. Some have attic perforations and some a polypus, and these are more difficult, yet usually possible, to cure. Most men have had the discharge lasting over many years, and the only treatment they have had has been hydrogen peroxide or glycerin of carbolic drops, no attempt being made to clean the ear before using these. The object of this note is to condemn all treatment that does not first involve dry cleaning of a discharging ear, and to give the family physician an easy method of cure. The treatment I adopt is as follows:

Method

I give each man 24 "peerless wood applicators," which can be repeatedly boiled, or, if the meatus is small, a fine metal probe; an ounce packet of long-fibre cotton-wool; freshly prepared boric-iodine powder (Lederman, 1917) and, if the perforation is small, a Fowler auto-insufflator, which acts like a Politzer bag; a powder-blower; and a bottle of liquid paraffin and an eye-dropper. I spend some time teaching each man to lay a thin transparent plaque of cotton-wool 3 in. long on the first and second fingers of the left hand, to lay the stick or probe on the cotton, and then to place his thumb, touching the first and second finger-tips, over the stick, so that the two fingers and thumb encircle two inches of the cotton and stick; and, finally, grasping the proximal inch of cotton with his right fingers and thumb, to rotate the cotton and stick, not moving his left fingers. The method of preparing boric-iodine powder is described by Carruthers (1943), while the method of preparing the cotton-covered stick is illustrated in five pictures in the same book.

I then teach the man how to straighten the external auditory meatus. If the right ear is affected I tell him to put his left hand over (not behind) his head and grasp the tip of the right ear with the first finger and thumb of the left hand, and pull the ear upwards, keeping the ear in contact with the skull, and then slightly backwards. The man is then told to rest his right hand on his cheek, and, holding the cotton-covered stick with his fingers, to worm it gently two inches into the ear, and repeat this cleansing process until the cotton returns clean or covered with blood. If the perforation is small the patient then uses Fowler's auto-insufflator—which blows the pus out of the middle ear—and repeats the cleaning process. He next takes up a powder-spoonful of boric-iodine powder, and, still keeping the meatus straight, blows the powder into the ear.

The above treatment is carried out three times a day. The patient is instructed never to let water enter the ear, and so before he immerses his head under water he fills the ear with liquid paraffin and plugs it with cotton-wool. He is also told never to turn his ear into an incubating-tube by wearing cotton-wool in it. This treatment usually cures a chronic otitis media in two or three weeks.

As an alternative treatment one can fill the ear with a suspension of sulphanilamide (1 g. to 30 c.cm.). This method is especially good with young children who will not tolerate the ear being cleaned, as they can lie on the bad ear for 15 minutes to empty it, and have this treatment done, after which cotton-wool can be applied.

Banham (1944) has recently published two prescriptions as an alternative to boric-iodine powder; one contains sulphapyridine as well as boric-iodine powder, while the other has equal parts of sulphathiazole and boric acid powder. Hollender (1943) recommends sulphanilamide, provided it be mixed with boric acid powder, for if used alone it forms an obstructing cork. The choice between sulphanilamide and sulphathiazole depends on the bacteriological nature of the discharge—sulphathiazole being used in the presence of a staphylococcic or pneumococcic infection, and sulphanilamide in the presence of a streptococcic infection.

The first and second treatments described have allowed many recruits to pass into the Forces.

A Case of Gunshot Wound of the Abdomen

The case described below is remarkable for the length of bowel resected at operation, and also raises the question of the dosage of morphine that should be used for the severely injured.

CASE NOTES

An Indian sepoy aged 24 was brought to a mobile surgical unit 18 hours after he had received a rifle-shot in the abdomen. On examination he was found to have a ragged wound in the right iliac fossa through which a large mass of intestines was protruding. This had been covered with a shell dressing. He was accompanied by a medical officer, who said that when brought to him some two or three hours previously the patient was so distressed that it was decided to give him a large dose of morphine. As it was impossible to have a light at the time, the medical officer was uncertain how much morphine he was giving, but he believed it was from 1/2 to 1 gr. No attempt had been made to resuscitate the man with plasma. His condition when seen by us was very poor. His breathing was slow and shallow and his pulse rapid and feeble. He was fairly alert mentally, and did not appear to be very uncomfortable. He was given atropine 1/50 gr. hypodermically and was taken to the theatre for operation without delay. Anaesthesia was induced with ethyl chloride, followed by ether on an open mask (Ogston's). Carbon dioxide had to be used for adequate breathing, and nikethamide (coramine) was injected hypodermically and intravenously (1.7 c.cm. each). An intratracheal tube was passed under direct vision and oxygen was given throughout.

The wound was enlarged and practically the whole of the ileum was found to be prolapsed. It was also perforated in a number of places and was gangrenous. Twelve and a half feet of the small intestine from the ileo-caecal valve upwards was rapidly resected, and the proximal end was inserted into the transverse colon, the distal end being invaginated into the caecum. Sulphanilamide powder was introduced into the peritoneum and the wound was closed, with a drain into the recto-vesical pouch. During the operation one pint of plasma was given by drip.

Convalescence was complicated only by sepsis in the wound. The general condition of the patient was remarkably good throughout, and he spent the first few days wondering why he was not getting his bowels open and why he was denied his rice and vegetables. A continuous intravenous drip saline was maintained for four days with sulphapyridine in each bottle, and an unsuccessful attempt was made to keep a Ryle tube in place. The patient was evacuated in very good condition on the seventeenth day.

COMMENTARY

This case brings out a point which has been learned by experience—namely, that in abdominal wounds more than six hours old it is undesirable to postpone operation for the sake of resuscitative measures however grave the patient's condition may be. In this case plasma was given as early as possible, but the operation was not delayed in the hope of an improvement in the general condition.

Although a large dose of morphine is by no means ideal in such cases from the anaesthetist's point of view, it might well be argued that this patient would not have survived to reach the surgical team had not a large dose of morphine been given. In view of the variety of ways in which individuals react to morphine it is not suggested that the use of a massive dose, as in this case, should be indulged in as a routine, but it is perhaps reasonable to speculate that this was one of those fortunate people who apparently react wholly favourably to morphine, and that it enabled him to survive this extremely severe injury and operation.

YEARBOOK OF UROLOGY

The 1944 Year Book of Urology. By Oswald S. Lowsley, M.D., F.A.C.S. (Pp. 416; illustrated. 18s. 6d.) Chicago: The Year Book Publishers; London: H. K. Lewis and Co.

Although urological research has been severely restricted by the war, the *1944 Year Book of Urology* does not appear to have suffered. It is as full of interesting material as its predecessors. Perhaps the only reminders in its pages that the world is at war are the absence of any reports or papers from clinics in occupied Europe, and the appearance of a special article on the use of penicillin in the treatment of urogenital infections. This article, by Capt. L. R. Reynolds and Lieut.-Cmdr. Weyrauch, is based on observations made on a very large series of cases examined in various hospitals of the U.S. Navy. It is particularly worthy of attention. There can be no doubt that penicillin is of inestimable value in the treatment of gonorrhoea, especially in those complicated cases in which the sulphonamides have proved successful. A course of 100,000 units of penicillin will bring about a cure in well over 95% of all patients with uncomplicated gonococcal urethritis if the drug is given in ten doses of 10,000 units every three hours. In the treatment of non-gonococcal infections the effect of penicillin is unfortunately much less impressive.

The *Year Book* also contains interesting articles on the surgery of the kidney and the adrenals. Dr. S. F. Wilhelm of New York has planned a new technique for operations on cases of obstruction at the pelvi-ureteric junction. Instead of implanting the divided ureter into the pelvis he splits the end of the ureter and implants the pelvis into it, thus avoiding the possibility of forming an obstructive flap. Drs. E. S. Judd and F. Z. Havens of the Mayo Clinic contribute a useful article on the treatment of the traumatic avulsion of the skin of the penis and the scrotum. They describe the use of both grafts and plastic operations. Dr. L. E. Sutton of Syracuse University gives an account of a case treated by first carrying out a perineal urethrotomy and then burying the denuded penis under the skin of the abdominal wall. All these articles are beautifully illustrated, and the *1944 Year Book of Urology* maintains the high standard of its predecessors.

PHYSICAL MEDICINE

Physical Medicine in General Practice. By William Bierman, M.D. (Pp. 654; illustrated. 37s.) New York: Paul B. Hoeber, Inc.; London: Hamish Hamilton.

Before reviewing any book it is customary for the reviewer to read the preface with some care, so that the intentions of the author and the scope of the work may be gathered. On this occasion it was decided to go through the book and then, as it were, write a preface for it, as found by personal study. On doing so, three outstanding impressions were left: first, that here was a book that gave an accurate, comprehensive, and yet fairly judicial conspectus of the possibilities of physical medicine for general practitioners who wished to be well informed on the subject; secondly, there jumped to the mind the old Chinese proverb that "A picture is worth a thousand words," because the numerous line illustrations throughout the book seemed to clarify some point of technique or help the practitioner to visualize some special position of patient or apparatus; and, thirdly, that those techniques which need considerable "filling out" have suitable references at the end of each chapter. It was interesting to find, on reading the preface, that all these three points were particularly emphasized by the author.

Though the book keeps closely to its original aim of being informative for general practitioners, there are here and there useful practical hints on technique that can with advantage be absorbed by the physical-medicine specialist or the physiotherapist. Considering the size of the volume there are extremely few techniques or statements that are not consistent with the best British practice in this field. The technique illustrated on page 156 (Fig. 91) is not one that would be considered free from risk of burn in England, while that in Fig. 92 would be considered a safe and useful method. It is also rather curious that in the section on hyperpyrexia there is no mention of the Kettering hypertherm, which is the American apparatus found most useful in England for this form of treatment. But these exceptions are few, and the book certainly well fulfils the purpose of the author. It may therefore be recommended with confidence—primarily to general practitioners, but also to technical experts in this subject, whether consultants or medical auxiliaries.

A PARENTS' GUIDE

The Intelligent Parents' Manual. A Practical Guide to the Problem of Childhood and Adolescence. By Florence Powdermaker, M.D., and Louise Ireland Grimes. (Pp. 256. 10s. 6d.) London: William Heinemann Medical Books. 1944.

This is an American book, but it has been anglicized by Dr. Newfield—a necessary proceeding these days. As it stands it is a most admirable volume which gives sensible information on the upbringing of the child at all stages of its development. If every parent would behave in the way recommended here no young person could complain that he had not had every possible chance to start well in life, and if any difficulties remained they must be due to inherent defects of one sort or another in the child. The progress of mental and physical growth is dealt with in considerable detail up to 6 years of age; thereafter school life and adolescence are discussed in more general terms, though the answers to most of the problems which arise between 6 and 16+ are to be found. Perhaps the most important and necessary exhortation is that parents and elders generally should respect their children. Respect is generally demanded but seldom given. It would be easy for individual readers to pick on minor faults in the text, but these are of no significance when compared to the general excellence of the book. Doctors are so often asked to recommend a useful guide for parents, and they need have no hesitation in recommending this volume—small and compact, clear in diction, free from technicalities, and comparatively cheap.

PHYSIOLOGY

Handbook of Physiology and Biochemistry. By R. J. S. McDowall, M.D., D.Sc., F.R.C.P.Ed., Professor of Physiology, King's College, London. Thirty-eighth edition. (Pp. 898; with 305 figs. 25s.) London: John Murray.

The present edition represents an interesting milestone in the progress of this, the oldest textbook of physiology in our language, for the name of Halliburton is now dropped from its title, and that of Prof. McDowall, who has edited the book for the past thirteen years, remains. The book, originally *Kirkes's Physiology* when it first appeared in 1848, was for many years known as *Halliburton's Physiology*, and will henceforth be called *McDowall's Physiology*.

During the editorship of the present editor the book has been almost rewritten, and the title was altered by the addition of the words "and Biochemistry" at the 35th edition, which appeared in 1937. In the opinion of the reviewer this addition was unfortunate, since the book cannot pretend to be a handbook of biochemistry, for it merely contains, and quite properly contains, those allusions to biochemical matters which are indispensable to the proper understanding of physiology. Some 80 new illustrations are added to the present edition, and one is glad to note the dropping of the elementary histological matter of the previous editions. This subject, like biochemistry, is best dealt with in separate works, though its value to a full understanding of physiology is beyond question.

The general quality of the production is first-class, and there is a good index.

Notes on Books

EDMUND B. SPAETH'S *Principles and Practice of Ophthalmic Surgery* (Henry Kimpton; 50s.) has quickly established itself as a standard book in English on the surgery of the eye. Though the third edition is published within three years of the previous one, it shows extensive revision, in both additions and deletions. The book now reads more evenly, and much of the jerkiness of the earlier issues has disappeared. The most extensive additions deal with squint and the experiences gained during the war in the treatment of injuries. It is to be hoped that future editions will accentuate the tendency shown by the present one, with its greater emphasis on the author's personal experiences as against a merely encyclopaedic presentation.

Bentley and Driver's Textbook of Pharmaceutical Chemistry, revised by JOHN EDMUND DRIVER, Ph.D., M.Sc. (London: Oxford University Press; 21st.), is a manual for students in pharmaceutical chemistry which has a high reputation and one which the new (fourth) edition will maintain. This edition includes the substances which have become official by their inclusion in the five Addenda to the *B.P.*, 1932, which have now appeared. For those doctors who are interested to have a readable and not bulky reference book on the chemistry of pharmacopoeial substances this work can be recommended with confidence.

Whitaker's Almanack for 1945 has now been published from 13, Bedford Square, London, W.C.1, after some inevitable delay. The usual three editions will be available—the complete edition, cloth bound, with 1,052 pages, at 10s.; the shorter edition, paper bound, with 704 pages, at 6s.; and the library edition, bound in leather, at 21s. Postponement of publication has enabled the editor to include a New Year Honours List as a supplement to the index, which now runs to 90 pages.

The British Journal Photographic Almanac for 1945, published at 5s. by Henry Greenwood and Co. Ltd., 24, Wellington Street, Strand, W.C.2, contains much of practical interest to photographers, both amateur and professional, and includes an article on the causation and prevention of photographic dermatitis by Dr. L. B. Bourne, medical officer to A. C. Cossor Ltd.

Preparations and Appliances

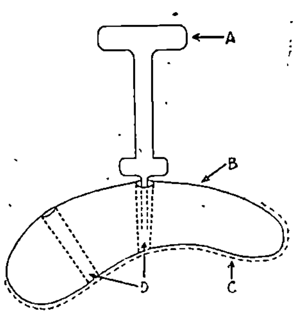
A NEW METHOD AND APPLIANCE FOR GRAFTING EYE SOCKETS

Mr. H. P. PICKERILL, C.B.E., M.S., F.R.A.C.S., writes from Wellington, New Zealand:

In 1919 I had the privilege of giving a clinical demonstration before the Oxford Ophthalmological Congress of the grafting of an eye socket disorganized by gunshot wound, to prepare it for the reception of a glass eye. From then until two years ago I, and probably all other plastic surgeons, have continued to use the same method—i.e., removing all scar tissue, dilating the soft tissues, and pressure grafting on stent or other substance—but the great difficulty then was to get a glass eye to fit the socket one had made, and glass eyes are still undoubtedly much superior to other materials. It never dawned on me until two years ago to reverse the process—to make all sockets to fit stock-sized glass eyes!

Material and Procedure

1. A stock-sized glass eye of the right colour is obtained.
2. This is enlarged a little with wax and then duplicated in acrylic resin—by taking moulds in stent, plaster, or gelatin.
3. Two holes are drilled through this acrylic mould, the same size as the nozzle of a Record syringe. One hole is drilled in the exact spot of the centre of the pupil. Into this hole is fitted a pin about 1½ in. long with a little shoulder on it to prevent it going too far in.
4. The socket is then prepared in the usual way. A half-thickness skin graft is cut with the dermatome and fixed on the acrylic mould, which is inserted in the socket.
5. The pin is inserted and fixed with strips of strapping from forehead to cheek and nose, so that it and the future pupil will be in correct position. The lids should also be sutured together, if indicated. If a dental splint can be used for fixation so much the better, but artificial dentures frequently prevent this.



6. In ten days' time some discharge appears. The pin is removed and the socket gently syringed (through the holes provided) with saline (later with boric lotion), the pin and strapping being replaced.
7. The appliance is retained in position for one month; it may then be removed every other day for cleaning and reinserted, pressure being kept up by elastoplast strips. In two months (minimum) the appliance can be discarded and the stock glass eye will be found to fit perfectly.

In the accompanying sketch A points to the pin made of 1/2 round stainless steel wire; B to the section of acrylic mould; C to the skin graft; and D to the holes drilled for syringing and reception of pin.

There is no co-ordinated movement, of course, but I have never seen any grafted eye socket in which such movement was possible. The method gets over the almost insuperable difficulty of having a special eye made for every grafted socket.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY APRIL 28 1945

INDUSTRIAL TOXICOLOGY

After the Medical Research Council reconstituted the Industrial Health Research Board in 1942 it took the very wise step of setting up a new department of industrial medicine at the London Hospital under Dr. Donald Hunter, who gave a vivid account of the work of his department about six months ago.[1] Some of the examples of industrial poisoning he then quoted were dealt with in much detail in his Croonian lectures, published first in the *Quarterly Journal of Medicine*[2] and subsequently in book form.[3] Long and bitter experience has taught those who work on problems of industrial medicine that substances of the highest value in production processes often have, by very reason of their valuable chemical and physical properties, a high capacity for harm to living tissue. Scientific knowledge of these properties, of their correlation with specific tissue injury, of their mode of entry into the body, and of their predilection for certain tissues and organs—this is the principal means of widening the field in which substances already in use can be applied to new processes and new agents can be introduced without increasing the danger of exposing industrial workers to their influence. On these principles are based the whole system of prevention of such danger and of adequate treatment if in spite of precautions injury should occur. And of perhaps greater importance is the thorough training of the industrial doctor in the principles and practice of clinical medicine.

The physical form or chemical constitution of a substance may greatly influence its toxicity. Many metals are comparatively inert in the form of powder but are highly toxic when inhaled as fume. Thus nickel is in itself not toxic, but as the gaseous compound nickel carbonyl it may cause severe congestion and oedema of the lungs. The influence of valency of the metal radical on its toxicity is exemplified by chromium, where toxic action is confined to the hexavalent compounds. Trivalent chromium salts, such as the phosphate and carbonate, are harmless, but the hexavalent compounds used in chromium plating attack the skin and nasal mucous membrane, causing chrome ulceration and perforation. Inorganic and organic compounds of the same metal may have a completely different toxic action, as seen in the case of lead and arsenic. The classical picture of lead colic, anaemia, and palsy of inorganic lead poisoning differs profoundly from the cerebral manifestation of intoxication with tetra-ethyl lead, while the local irritation of mucous membranes set up by contact with the dust of arsenic is a far less serious injury than the acute haemolysis caused by arseniuretted hydrogen. The chemical constitution of some of the more complex organic members of the aromatic and chlorinated hydrocarbon groups is sometimes an indication of their probable toxicity. Thus the addition of a nitro or nitroso group to the benzene ring usually produces a more toxic compound; the ortho-isomer of tri-cresyl phosphate is more dangerous than the para- or meta-isomer; the toxicity of the chlorinated hydrocarbons rises with the molecular weight, though subject to a compensating decline due to decreasing volatility.

The two chief paths of entry of industrial toxic substances into the organism are by inhalation and through the skin; and, generally speaking, inhaled toxins exert the maximum effect, with a clinical picture sometimes differing in many respects from that produced by skin absorption or ingestion. The erethism of poisoning by mercury vapour—a mental syndrome of suspicion, timidity, fear, and irrational behaviour—is practically never seen in the "mercurialism" of therapeutic administration; most cases of acute occupational poisoning by nitrobenzene and aniline arise through skin contamination, whereas in benzene poisoning inhalation is by far the most important channel, as also with "narcotic" substances such as trichlorethylene and ethylene dichloride. The polyneuritis of tri-cresyl phosphate poisoning, however, is practically identical whether caused by inhalation of the fumes or, as in the "Jake paralysis" in America in 1930, by ingestion of an adulterated beverage.

The predilection of any given toxic agent for any specific organ or tissue appears to depend on all these factors and their various combinations. The affinity of the "narcotic" poisons, such as trichlorethylene, for the higher centres of the central nervous system is that of all anaesthetics; the specific action of benzene on the bone marrow may be an expression of its outstanding lipoid-solvent power; the cyanosis of T.N.T. poisoning an expression of the affinity of many of the aromatic nitro and amino compounds for the oxygen of oxyhaemoglobin; the so-called "aniline" cancer of the bladder may be associated with the chronic trauma caused by excreted irritating decomposition products; the "chloracne" of chlorinated naphthalene wax is a result of irritation of the sebaceous glands by chlornaphthalene followed by hypersecretion and plugging; the loss of weight, sweating, and high temperature of poisoning by dinitrophenol are due to the fact that it is a strong stimulant of metabolism. The special susceptibility of the liver and kidneys to some of the chlorinated hydrocarbons and of the kidneys to at least one member of the glycol group, dioxan, has not so far been fully explained. Certain it is that many of the halogenated organic compounds are recognized liver poisons. The clinical picture, first and most clearly seen during the last war from the use of tetrachlorethane as an aeroplane dope, is that of toxic jaundice from acute necrosis of the liver. The combination of liver and kidney injury has occurred chiefly from the use of carbon tetrachloride as a fire extinguisher, while ethylene dichloride has also a nephrotoxic and hepatotoxic action, though less than that of carbon tetrachloride and tetrachlorethane. Diethylene dioxide (dioxan) may also cause enlargement of the liver, but in fatal cases the liver injury was overshadowed by acute haemorrhagic nephritis. How far personal or organ susceptibility determines toxic action is uncertain, but undoubtedly it does exist. Cases of benzene poisoning may occur, for instance, in only a few individuals of a large number similarly exposed, or in some receiving comparatively slight exposure. Age and sex appear to be less important factors than weakness of the general constitution or of special organs or systems. From this point of view no worker with considerable abnormality of the blood picture should be exposed to benzene; nor with liver insufficiency to carbon tetrachloride or trinitrotoluene; nor with albuminuria to ethylene or diethylene dioxide; nor with a sensitive skin to arsenic or tetryl.

[3] *Industrial Toxicology*, 1944, Oxford, The Clarendon Press. (Pp. 80. 10s. net.)

One of the most recent tendencies in the progress of industrial hygiene is the choice of persons for particular work with regard to such special susceptibility, and it is a measure which might well be further encouraged as a means of preventing injury by toxic substances. Medical supervision, with periodic medical examination, of workers in various hazardous industries has also made great progress since its compulsory application to firms employing a large number of workers and its voluntary adoption by many smaller firms. These measures, together with provision of adequate ventilation, insistence on personal cleanliness of workers, and general hygienic conditions of workshops, have gone far towards reducing the risk to health arising from exposure to substances whose toxicity is recognized and understood. It is to be hoped that new compounds will be fully tested before being used in production, and that ever-increasing efforts will be made to substitute any found to be comparatively innocuous for those whose ill effects on the industrial workers must surely outweigh their value as technical aids to industry itself.

SOCIAL SERVICE IN WARTIME

The more reconciled the British people become to State intervention in social concerns the more strongly do they appear to cherish the voluntary principle. Even if State control and provision were complete it would only mean the release of voluntary agencies for the opening up of new fields. The war, which has seen such a great regimentation of the nation, has seen also the spirit of voluntary service rise to new occasions. This is well illustrated in the experience of the National Council of Social Service, which has lately issued a report covering the last twenty-one months of its work.[1] In 1938, at the time of Munich, the National Council called a number of voluntary bodies into consultation in view of the expected disorganization of social life in the event of war. An effort was then made, as the report says, "to plan our services so that their maximum potential would be released in the hour of need." The subsequent story makes a fine record, though not in the least a dramatic or spectacular one.

The work has taken a highly complex pattern—citizens advice bureaux, youth organizations, old people's welfare, communal feeding, women's social service clubs, the institution of training schemes for social workers, and many other activities, diverse in their nature but directed to the same end. One recent development is the setting up of machinery for maintaining a close relation between the National Council of Social Service and the National Council for Maternity and Child Welfare. The one body will make available to the other its various services and contacts so far as these are relevant to the other's objects; duplication of services will be eliminated and activities extended as far as this liaison makes it possible. Another field in which the National Council has been engaged is a study of the post-war holiday problem—a problem which may be much more serious than it appears to be at a casual glance. After the tension of war years there will be a tremendous demand for holidays—a demand increased by the holidays-with-pay arrangements—and unless something is done by way of organization and control there is likely to be an overwhelming congestion at holiday centres, with such wear-and-tear of body and frustration of spirit as will make the holiday of less than no value to many who flock to the coast. The National Council suggests that it is a task for the Government to establish a national holidays corporation which would make emergency provision, including the acquisition and control of wartime hostel and camp accommodation. Thus the British citizen who has had to submit to control of his industry during the war years may have still to submit to control even when he relaxes, and it will cheer him little to be told that this is for his own good. It may come to "coupons for holidays," but the words have an ugly ring in the ears of a free-born Briton.

Then there is the work which the National Council has undertaken in the rural areas. For years it has been drawing attention to the danger of the countryside taking second place in the facilities provided for social and community life. It has made grants and loans for the establishment of village halls; it has encouraged music and drama, helped rural industries, and has done much to increase interest in parish councils. Perhaps it is worth while to point out that there is another community standing in as great a danger of neglect as the 20% of the population who live in rural areas—namely, the neo-suburban community. We know of single estates of flats and houses under one ownership, situated around London and other cities, in which there may be a population of a couple of thousand, equal to that of a good-size village, but without any communal provision. A village of that population would have its church, two or three chapels, and perhaps a hall, not to speak of inns and clubs, but on these housing estates there is very generally no focus of community; and the matter is made worse because the people often have moved from in-town surroundings, where they had some sort of community centres, even if rather tawdry ones. But no doubt this problem, too, is in the mind of the National Council, which, under the chairmanship of the Warden of All Souls, has achieved so much in so many fields. This is the twenty-fifth year of the Council's work, and it is regarded as a turning-point in the development of voluntary service, marked by the growth of machinery for consultation among voluntary organizations pursuing like ends.

CONDITIONS FOR GOOD VISIBILITY

The visibility of an object depends on a variety of factors, such as its size, the illumination on it and its surroundings, and the contrast between it and its background, as well as on the state of adaptation of the eye by which it must be recognized. These factors are all related to one another in different ways; for instance, the level of illumination will affect the state of adaptation of the eye, or the smaller an object the more brightly must it be lighted to make it visible. Hence the determination of the optimum conditions for the performance of a visual task, whether in a factory, school, office, or home, is not always simple, and much information is usually needed before the most satisfactory results can be achieved. It is probable that in the majority of cases in which the problem arises the only factor in the set-up which can be varied will be the illumination, because the size and contrast of the detail making up the pattern of the task are usually fixed by its very nature, whether it be type-setting or hemming a handkerchief.

A method of attacking such problems can, as pointed out by Beutell, be "based on the proposition that the illumination required for any visual task, as compared with the simplest possible task, depends upon certain conditions adversely affecting its performance; that these conditions can be defined; and that if the relationship can be ascertained between each of the conditions and the illumination required to compensate for it, then the illumination suitable for the performance of the task ought to be capable of actual computation."[1] As a result of this suggestion of Beutell's a series of investigations into the effect of some of the variants of visual tasks on the relationship between illumination and visual efficiency was initiated and the first report, on the effect of size of work, published jointly by the Industrial Health Research Board and the Illumination Research Committee of the Department of Scientific and Industrial Research in 1935.[2] A second report, by H. C. Weston, has just been put out by the Industrial Health Research Board under the title "The Relation between Illumination and Visual Efficiency—the Effect of Brightness Contrast."[3] The task chosen for this set of experiments was the recognition of the position of the gap in a series of Landolt's broken rings under different conditions of illumination and contrast. Both "reverse" (light on dark) and "normal" (dark on light) contrast were used. The results, presented in an intimidating mathematical form, show that there is no constant relation between brightness contrast and the illumination required to ensure maximum visual efficiency. If the size of the task detail is great enough, and the contrast not too poor, differences in contrast will not affect performance. If, however, the size of the object to be recognized is small the amount of contrast it presents to its background is most important for visual efficiency. The lower the contrast the higher must the illumination be raised before a maximum performance can be obtained, but no amount of illumination can bring the performance of a task involving poor contrast up to the level of one where the contrast is good. From the practical point of view this means that, whenever possible, visual tasks which call for the recognition of fine detail should be arranged so as to give as much contrast as possible between detail and background. Where (and this covers a large number of cases) this is not possible, as, for instance, in sewing with a matching thread and particularly when the colour is a dark one, it is necessary to ensure that the lighting on the task is as good as it can be. It is interesting to note in passing that, under any given set of experimental conditions, a task in "reverse" contrast was performed better than one in "normal" contrast.

CARE AND TEACHING OF HANDICAPPED CHILDREN

Special educational treatment for handicapped children is dealt with in draft regulations published last week by the Ministry of Education and summarized on another page. Blind, deaf, epileptic, physically handicapped, and aphasic children will normally be educated in special schools. Blind and those epileptic children who need special educational treatment must be taught in boarding schools. Other handicapped children, including the partially sighted, the partially deaf, the educationally subnormal, may go to an ordinary school if they can have suitable special educational treatment there and if this would not be detrimental to the other children. Otherwise they too will go to special schools. Two new groups of handicapped children are recognized—maladjusted children and those with defects of speech; and power is given to local education authorities to maintain children at special schools up to the age of 19 instead of 16. Where it is necessary to board out a handicapped child with foster-parents the authority must arrange for inspections of the home. The work of the school medical service is to be much extended under the new Education Act, and research will be encouraged. The regulations provide for the medical inspection as soon as possible after admission of every child admitted to a maintained school for the first time, and, in the last year of his attendance, of every pupil at a maintained primary or secondary school. In all special schools and institutions not maintained by a local education authority every pupil must be medically and dentally inspected on admission and at least once a year. Another wise provision is that which requires every authority to appoint a senior dental officer.

HOSPITAL MEALS

The Ministry of Health has issued a circular to hospital authorities giving recommendations on catering. The circular has been prepared primarily with a view to the feeding of hospital staffs, but the recommendations apply with equal, if not greater, force to the feeding of patients. The need for a scientific approach to this subject—including judicious buying, good cooking, palatability, and attractive presentation—is emphasized. The most difficult recommendation is the first—namely, that where practicable the catering department of a hospital should be in the charge of a full-time and suitably trained officer, such officer to be responsible for ordering foodstuffs, framing menus, management and control of the kitchens, dining-rooms, and the ward meal service, and for supervision of special diets. In the smaller hospitals some combined arrangement may perhaps be made for the purpose. It is also recommended that this officer should be trained in nutrition and dietetics, or, in the large hospitals, that he should have one or more persons on his staff specially trained in these subjects. The difficulty seems to lie in the lack of trained persons. The British Dietetic Association, which is the qualifying body for the Board of Registration of Medical Auxiliaries, has a membership of some 277, of which dietitians and food supervisors in civilian hospitals number only about 100, and there are in Great Britain between 350 and 400 voluntary hospitals alone with over 100 beds. It is further suggested that hospitals should review the design and arrangements of kitchen and food store-rooms, and prepare for necessary improvements as soon as these can be undertaken. Adequate dining-room or mess-room accommodation should be provided for all the non-resident, as well as the resident, staff who want such facilities as hot meals or light refreshments or hot drinks. It is pointed out that hospital rations cover, and are designed to provide for, occasional meals for non-resident staff. An expert staff of the Ministry of Health and the Department of Health for Scotland and the Dietetic Advisory Service of the King Edward's Hospital Fund for London are freely available for the regular visiting of hospitals and for advice on catering improvements. The Ministry of Labour and National Service for its part is trying to meet the requirements of hospitals for domestic staff, and during the last twelve months 41,500 women and 3,300 men have been placed in hospitals or similar institutions in that employment. Certain courses of training have been arranged, particulars of which can be obtained from the Employment Exchanges to which hospital vacancies are notified. One is a training scheme for large-scale cooking and lasts for six or twelve weeks, according to the previous experience of those attending.

HUMAN REQUIREMENTS OF VITAMIN C

What is the minimal daily requirement of vitamin C necessary for good health? According to various workers this varies from 10 mg. to 100 mg., depending on the method of investigation. Those who use the saturation test as an index of vitamin-C nutrition recommend daily intakes of from 75 mg. to 100 mg. The rationale of this test is that after a large test dose the needs of the tissues for vitamin C are satisfied before it increases in the blood to the threshold value, when much more is excreted in the urine. The value of the saturation test has recently been questioned. There is no general agreement on how big the test dose should be, or on how the results should be interpreted; the threshold value for vitamin C varies widely from person to person; and Crandon's work on experimental scurvy[1] proves there is no evidence that saturation with vitamin C is necessary for health. As almost any concentration of vitamin C in the plasma appears to be compatible with good health,[2 3] the saturation test is not of much use in diagnosing vitamin-C deficiency or in computing the vitamin-C requirements of man.

More help is likely to come from estimation of the vitamin C in whole blood (not plasma) or in the white-cell–platelet or buffy layer of centrifugalized oxalated blood.[2 3] A constant level of the vitamin, no matter how low, indicates a positive balance; falling values point to a gradual depletion of vitamin C. There is no clinical justification for the view, commonly held, that a concentration of vitamin C above 0.6 to 0.7 mg. per 100 c.cm. of plasma is necessary for health. From measurement of the vitamin C in the white-blood-cell layer Pijoan and Lozner[4] have calculated the minimum requirements for man. One of these authors lived for twenty-two months on a diet providing 25 mg. or less of vitamin C daily. Although plasma vitamin C was only 0.0 to 0.2 mg. per 100 c.cm. and no vitamin C was being excreted in the urine, no ill effects were observed, and an experimental wound in the back healed normally. The white-cell–platelet content of vitamin C was constant at 26±2 mg. per 100 g. on a daily intake of 18 to 25 mg. It would therefore appear that good health can be maintained on a daily intake of 25 mg. of vitamin C. This may be regarded as the protective minimum, because on intakes below this figure Pijoan and Lozner found that the vitamin C in the white-cell–platelet layer showed a continuous fall.

In gauging the vitamin-C nutrition of the individual one must measure the vitamin content not of the plasma but of the tissues, and the best guide to this is whole blood or white-cell–platelets. Vitamin C in the plasma represents an overflow or a phase of positive balance, and it appears in the urine when the renal threshold value is reached. So it is thus possible to be in good health with a plasma vitamin C at or just above zero, and none in the urine. These observations of Pijoan and Lozner receive support from other quarters. Najjar and his colleagues[5] kept seven young adults on a constant daily intake of 25 mg. of vitamin C for eighteen months without finding anything abnormal by clinical or laboratory tests. Stamm, Macrae, and Yudkin[6] did not observe a single case of scurvy among 2,962 R.A.F. personnel on a diet containing from 17 mg. to 26 mg. of vitamin C daily. Farmer[7] also found that experimental scurvy could not be produced in human volunteers unless the daily intake fell below 10 mg. It would thus seem that approximately 25 mg. of vitamin C is the minimum daily requirement of the vitamin for the average individual. This will keep a positive vitamin-C balance. Whether there is an optimum intake higher than this, and, if so, how much, is a matter for conjecture.

THE QUESTION IS . . .

The publication some time ago of *Our Towns: A Close-up*[8] which was a disclosure of slum life as shown up by evacuation, disturbed the public conscience to an extent that far more ambitious social treatises have failed to do. The National Council of Social Service has now followed it up by a pamphlet prepared by the Women's Group on Public Welfare, and entitled *What Do You Think?*[9] which is a series of study-outlines based mainly on the earlier publication and intended for the use of discussion groups. The purpose is to get discussion going all over the country, not in large bodies but in groups of from seven to fifteen people. Discussion has been defined as conversation with a point to it, and it is believed that more useful results may be brought about in this way than by the holding of mass meetings, which create a great deal of sound but merely explode in air. This syllabus ranges over such questions as the family, the living wage, the house and its housekeeper, education, neighbourliness, the use of leisure, and good health. It is largely in the form of a series of questions, to some of which the answers are obvious—" Is it more economical to spend money on preventing illness or on curing it ? "—while others are more debatable. The groups are asked to say how to prevent noisy people from disturbing quiet people, and also how to prevent quiet people from irritating noisy people. Another provoking question is, " If some families refuse to take the trouble to achieve good health, what would you do ? " If discussion groups can be arranged it may mean that wider and wider circles of people will learn to think objectively, feel generously, and act in co-operation, and something may be done, beyond what any legislation can do, to remedy those social faults and incompetences on which *Our Towns* threw so lurid a light.

WARTIME INJURIES IN ENGLAND AND WALES

BY

PERCY STOCKS, M.D.

General Register Office

The disturbances in social conditions during the last five years, affecting the distribution, housing, and working conditions of the population, their means of transport, and the lighting of streets and buildings, might be expected to leave clear impressions upon the rates of mortality from accidental causes among civilians. For various reasons, such as unavoidable delays in publication of the Registrar-General's annual reports, little detailed information has yet been made available on this question, and a good deal of misconception exists in consequence. It may be that useful lessons for the future years of peace can be learnt from the behaviour of death rates from different forms of accidents during the war, particularly with regard to those occurring on the roads and in the home.

Furthermore, the war has brought us for the first time statistical information on an almost national scale regarding types of injury resulting from various forms of external violence and causing admission to hospitals. Plans for house-building, town-planning, road construction, and restoration of private motoring, hospital treatment, and rehabilitation of injured persons are all in the air, and it seems desirable that some information should be given now about accidents and fatalities in recent years. The trend of civilian mortality from various forms of violence in different sex and age groups will first be considered, and then the kinds of injury which have been found in patients admitted to E.M.S. hospitals, both from the Services and from the civilian population.

Civilian War Fatalities

The numbers of civilian deaths registered in England and Wales during the four years 1940 to 1943 and classified as due to operations of war (International List No. 197) were as follows:

	1940	1941	1942	1943
Males	11,691	10,798	2,044	1,571
Females	10,524	8,745	1,747	1,431

Of these 48,551 deaths, 39,727 were registered in the 12 months from July, 1940, to June, 1941, inclusive. They comprise deaths from injuries caused by enemy action and by manœuvres and practices for offence or defence, and the figures include women in the Services up to mid-1941, merchant seamen who died in this country, and the Home Guard. Nevertheless, the great bulk of the deaths resulted from haphazard night bombing; and had the population been distributed as in peacetime and remained within their homes the death rates might have been expected to vary little with sex and age except so far as these affected recovery rates after injuries not immediately fatal. When the death-rates of separate sex–age groups are expressed as percentages of the rate for the population as a whole, indices slightly below 100 up to age 55 followed by increases over 100 thereafter, and showing little sex difference, would have been anticipated if all groups of the civilian population had moved from their homes, resorted to shelters, and otherwise reacted to the situation in the same way.

TABLE I.—*Civilian Death Rates from Operations of War in 1940–3 for Different Sex and Age Groups, Expressed as Percentages of the Rate for Persons of All Ages in the Same Year*

Age Group	1940		1941		1942		1943	
	M	F	M	F	M	F	M	F
0–	63	58	68	66	55	70	57	62
5–	52	50	57	53	78	51	86	77
15–	124	82	141	77	122	69	112	69
45–	144	98	144	88	166	87	165	87
55–	156	111	165	97	163	102	167	104
65–	141	128	144	109	142	143	150	131
75+	157	168	138	130	171	194	177	162
All ages	115	87	124	81	123	81	91	64

Table I indicates how far the actual indices departed from this hypothetical position, and some inferences may be drawn from the differences. Children under 5 years of age experienced rates much more favourable than those of all civilians, to the extent of about 40% in 1940, 33% in 1941, 37% in 1942, and 41% in 1943. Children of school ages showed corresponding advantages of 49% in 1940, 45% in 1941, 35% in 1942, and 18% in 1943, their advantage diminishing as the dispersed children returned to their homes. Women reduced their rates by 1942–3 to 31% below the average at ages 15–45 and to 13% below average at 45–55. All other sections showed rates above the average, the excess increasing for men aged 45–65 to about 65% in 1942–3. The large excess for old people of both sexes was no doubt due partly to inability or disinclination to take shelter and partly to lower recovery rates from injuries not immediately fatal.

Civilian Road Fatalities

TABLE II.—*Civilian Death Rates from Road Accidents in 1939–43 for Different Sex and Age Groups, per Million Living*

	1939	1940	1941	1942	1943
Children:					
0–	95	121	152	130	97
5–	114	117	158	135	123
Men:					
15–	248	232	255	175	139
45–	253	260	265	200	166
55–	406	420	423	281	226
65–	634	631	607	469	349
75+	1,171	1,068	969	731	538
Women:					
15–	44	42	45	37	31
45–	52	52	59	41	36
55–	105	90	96	68	53
65–	223	167	178	130	99
75+	361	280	258	189	191
Persons all ages	177	168	181	136	110

Table II shows the civilian death rates caused by road accidents (International List Nos. 170, 171), which for persons of all ages changed little from 1939 to 1941, but declined considerably in 1942 and again in 1943. The decrease in road traffic might have been expected to affect all age groups to about the same relative extent, but it is important to notice that children did not share in the improvement in mortality, their rates being still slightly higher in 1943 than in 1939, after being very much elevated in the intervening years. At ages 15–55 males registered an improvement, starting after 1941, of about 40% from 1939 rates, and women about 30%, while people over 55 of both sexes showed progressive decline in death rates, until by 1943 they reached about one-half of the 1939 levels. Children suffered twice as heavily from road accidents in 1942–3 as from operations of war, and their continued high rate of mortality despite diminished road traffic is a matter which needs serious consideration in post-war planning.

Accidental Deaths in the Home and Elsewhere

TABLE III.—*Civilian Death Rates from Violent Causes, other than Operations of War and Road Accidents, in 1939–43 for Different Sex and Age Groups, per Million Living*

	1939	1940	1941	1942	1943
Children:					
0–	498	553	582	550	527
5–	104	125	147	135	133
Men:					
15–	359	412	424	403	415
45–	626	680	611	532	512
55–	975	1,019	872	745	688
65–	1,135	1,302	1,169	978	946
75+	2,801	3,159	2,612	2,381	2,108
Women:					
15–	100	98	115	100	99
45–	246	237	197	187	169
55–	367	389	327	282	256
65–	740	901	726	601	550
75+	3,122	3,526	3,061	2,680	2,456
Persons all ages	411	458	434	392	379

Death rates from "other" accidents are shown in Table III. In 1940 they increased for every group of the civilian population except women aged 15–55. In 1941 further increases occurred for children and young adults, but at ages over 45 the rates declined consistently year by year from 1940 to 1943. As in the case of road accidents, children's mortality in 1943, although below that of the two years preceding, was still above 1939 levels. This was true also of men under 45, but every age group over 45 for each sex registered pronounced improvement in 1942 and further improvement in 1943 on the 1939 rates. Here again, why should the mortality of young children have risen by 5%, and of school-children by 28%, while that of men and women at ages over 45 declined by 20 or 30%?

Table IV.—*Deaths of Civilians from Accidents known not to be due to Industry or Transport, 1940–2 (see Text)*

	Year	Children 0–	Children 5–	Men 15–	Men 65–	Men 75+	Women 15–	Women 65–	Women 75+

	1941	2	3	18	—	—	2	1	—
	1942	1	3	19	—	—	4	—	—

Table IV throws some light upon the causes of those fatalities which occurred for the most part within people's homes during 1940, 1941, and 1942. From each group in the table have been excluded accidents in mines and quarries, those connected with transport, machinery, and operations of war, and those indicated as occupational, apart from housework. The great majority of the residual deaths must have been due to accidents at home. Considerable numbers of coroners' certificates furnish no clue to the circumstances in which the accident occurred, and an unknown proportion of deaths classified to burns, fall, crushing, and "other" accidents of "unstated cause" must also have occurred at home. The totals in these groups are shown in Table IVa, and need to be considered in conjunction with the better-defined deaths in Table IV.

Table IVa.—*Deaths of Civilians from Certain Accidents in Unknown Circumstances*

	Year	Children 0–	Children 5–	Men 15–	Men 65–	Men 75+	Women 15–	Women 65–	Women 75+
Burns of unstated cause	1940	67	26	26	20	34	63	41	63
	1941	41	26	24	13	23	49	38	40
	1942	47	36	14	13	19	40	24	44
Fall, crushing, other and unspecified*	1940	51	67	602	207	321	142	260	739
	1941	34	56	391	159	292	102	222	666
	1942	40	39	238	129	220	87	143	549

* Including "fracture of leg" at ages 65 and over.

For children and old people the combined tables must represent the totals of home fatalities without much overstatement, and it is safe to conclude that about 1,150 children, between 1,100 and 1,300 people aged 15–65 and between 3,200 and 3,400 people aged 65 and over died from such accidents in 1942. Burns and scalds contributed about 400 to this total for children, compared with about 500 in 1940, and suffocation in bed or by food contributed about 500, compared with about 450 in 1940.

Types of Injury causing Admission to E.M.S. Hospitals

The hospital records of patients admitted to E.M.S. beds are sent after completion of treatment to the Ministry of Pensions registry at Norcross. At the end of 1942 work was begun on these records by a small statistical staff of the E.M.S. organization in order to gather information about the frequency of various diseases and injuries—not merely for historical purposes but also to dispel some of our ignorance about such important matters as the types of injury produced by different forms of violence and the durations of hospital treatment and disablement resulting therefrom. For this purpose every fifth patient was selected by a random process from those admitted to all E.M.S. hospitals, starting from 1942, and the final diagnoses of the principal disease or injury causing admission, and of the chief complications and associated conditions, were coded by means of the Medical Research Council's Provisional Classification of Diseases and Injuries (Special Report No. 248). These codes and the essential details of sex, age, occupation, duration, etc., were entered on cards, and more than 120,000 have been thus dealt with up to the present. Owing to the long stay in hospital of some patients, tabulations of the admissions during a given year cannot be made finally until about 15 months has elapsed from the end of that year, but statistics for the years 1942 and 1943 are now becoming available, and form the basis of the tables which follow. After the war 1940 and 1941 will, it is hoped, be dealt with, but at present nothing can be said about those years.

Civilians injured by enemy action and admitted on that account to E.M.S. beds must have numbered over 7,500 in 1942–3, since the one-fifth sample used in Table V comprises 1,530 patients, 881 being males and 649 females. The table distributes these according to 18 main injury groups, expressing the frequencies in each sex as percentages of the totals. Open wounds without injury to bones, nerves, or internal organs formed 37% of the injuries of males and 40% of those of females, and bruises and contusions formed about 7% for each sex. Fractures were present in 23% of injured males and 20% of females, and head injuries without fracture in about 12 and 13% respectively. Lower-limb and skull fractures, burns, and traumatic amputations were relatively more frequent in males

Table V.—*Types of Injury Sustained in the United Kingdom by Civilians through Enemy Action, and by Men and Women in the Services through Accidents, causing Admission to E.M.S. Hospitals in 1942–3*

than in females, while upper-limb fractures and crush injuries occurred more often in females.

Non-civilians injured by accidents of various kinds are dealt with in the same way in Table V. "Accidents" include those occurring during training and manœuvres as well as those happening while off duty, the only injuries excluded being those due to enemy action and those purposely inflicted by self or others. The external causes distinguished in the table for men are explosive missiles (M.R.C. suffix codes 4V to 6Y), road accidents (suffix 1 to 7), sport (suffix 4X), and all other accidents. About one-third of the last-mentioned group of accidents were said to have been falls or blows, and considerable numbers are included here concerning which the hospital records gave insufficient information about the accident to allow classification to the specific external cause.

* Without fracture or more serious injury.

† Includes burns, foreign bodies, poisoning, traumatic amputations, and "others" in Table V.

Of the injuries accidentally caused by explosive missiles during exercises or otherwise 6½% were head injuries, 13% lower-limb fractures, 9% upper-limb fractures, 5½% other or multiple fractures, 2½% traumatic amputations, and about 5% involved large nerves. Of the injuries received during sport 8½% were head injuries, 20% lower-limb fractures, 11½% upper-limb fractures, 2% other or multiple fractures, 3½% dislocations, and 50% were nothing more than sprains, strains, or contusions.

Road accidents produced higher proportions of head injuries and of spine and trunk fractures, no less than 6% having a skull and 2% a spinal fracture. In Table VI this sample of 3,054 road accidents to men is analysed according to whether the patient was on a motor-cycle, driving or riding in a motor vehicle, riding a bicycle, or involved as a pedestrian. Motor-cyclists' injuries consisted of skull fractures in 4½%, other head injuries in 13½%, lower-limb fractures in 25%, and other fractures in 23%. Both drivers and passengers of other motor vehicles show higher percentages of skull fractures (9½ and 7), of other head injuries (34 and 24), and of spine and trunk fractures, than do the motor-cyclists, but their liability to lower-limb fractures is much less (6 and 7). Pedal-cyclists show high proportions of upper-limb fractures and minor head injuries compared with motor-cyclists.

The types of injury sustained by women in the Services are shown in the final column of Table V, based on a sample of 712. The distribution differs from the "other accidents" group of men by an excess of burns and minor head injuries and a corresponding deficiency of limb fractures.

I. L. Applebaum (*Ann. intern. Med.*, 1944, **21**, 35) records his observations on serum amylase in 65 controls and 60 cases in which mumps was diagnosed. He found high amylase levels in 95% during the acute stage, but in exceptional cases the results may be capricious and the clinical symptoms must be relied on.

EDUCATIONAL TREATMENT OF HANDICAPPED CHILDREN

Special educational treatment for handicapped children, including arrangements for boarding out with foster parents, and the school medical and dental services, are among the subjects dealt with in new draft Regulations published by the Ministry of Education (H.M. Stationery Office; 4d.).

Provision for Handicapped Children

Where it is necessary to board out handicapped children with foster parents local education authorities must arrange for the inspection of the home before the admission of the first pupil, during the first month of residence of each pupil, and at least once a term afterwards. Authorities are advised to employ if possible a trained social worker or a school nurse with the qualifications of a health visitor for this purpose.

In a circular for the guidance of authorities (Circular No. 41, H.M. Stationery Office; 2d.), the Ministry of Education points out that the boarding of children under good conditions away from their homes often constitutes an important element in special educational treatment, particularly in the case of maladjusted children.

All blind, deaf, epileptic, physically handicapped, and aphasic children will normally be educated in special schools. Blind and those epileptic children who need special educational treatment must be educated in boarding schools. Other handicapped children, including the partially sighted, the partially deaf, the educationally subnormal, and those suffering from other physical handicaps, may be educated in ordinary schools if suitable special educational treatment can be provided, and if this would not be detrimental to the other children. Otherwise they too will go to special schools.

Methods of Treatment

The methods of treatment to be provided for various types of pupil in ordinary schools will include the following:

(i) For the partially sighted, a favourable position in the classroom and the provision of special furniture, apparatus, and equipment.

(ii) For the partially deaf, a favourable position in the classroom, the provision of individual hearing aids if necessary, and tuition in lip reading.

(iii) For a delicate child, education under favourable hygienic conditions, with special provisions for nutrition and rest.

(iv) For a diabetic child, residence in a hostel under medical and nursing supervision.

(v) For educationally subnormal children, tuition adapted to their special needs, either individually or in small groups or classes, including adequate facilities for practical work.

(vi) For maladjusted children, such special educational treatment as may be considered appropriate by an educational psychologist or other suitably qualified person employed by the authority, or by a child-guidance centre or clinic.

(vii) For a child suffering from speech defect other than an aphasic child, special training and treatment by a duly qualified speech therapist.

In the past it has not been possible for education authorities to maintain children at special schools after the age of 16, but in the future, if an authority wishes and the parent consents, a child may stay at a special school up to the age of 19.

Pending arrangements to be made by the Ministry of Labour under the Disabled Persons (Employment) Act, 1944, the existing arrangements for vocational training of certain types of seriously disabled persons will continue to be approved by the Ministry of Education.

Medical Inspection

The regulations dealing with the school medical service provide for the medical inspection of children in all schools maintained by education authorities as follows:

(i) Every child admitted to a maintained school for the first time shall be inspected as soon as possible after admission.

(ii) Every child attending a maintained primary school shall be inspected during the last year of his attendance.

(iii) Every child attending a maintained secondary school shall be inspected during the last year of attendance.

The Minister may give directions for additional medical inspection, and it is open to authorities to arrange for this if they have the necessary staff. In the case of all special schools and institutions not maintained by a local education authority all pupils must be medically and dentally inspected on admission and at least once a year—in the case of open-air schools and schools of recovery for delicate children, once a term.

For the first time authorities are required to appoint a senior dental officer. This is to ensure that there shall be one officer on the staff of the school medical service responsible for the organization, development, and technical efficiency of the school dental service.

Provision is also made for encouraging the use of the school medical services for research. Much valuable work in problems of child health has already been done by school medical and dental officers, and the Minister is anxious that such research should be continued on an even wider scale. Authorities are urged to encourage the work and to co-operate with university departments such as those of child health, social medicine, and public health.

Another new requirement is that all school nurses appointed in future must be qualified as health visitors. This is to facilitate interchangeability of staff and the co-ordination of the school medical service with the maternity and child welfare service and the general health services of the future, and to promote efficiency in administration and to secure continuity in the care and supervision of children. This regulation will not apply to specialists such as masseuses and remedial gymnasts.

ALLOWANCES TO INVALIDS AND PERSONS NEEDING SPECIAL DIETS

The following changes in the arrangements for special allowances to invalids and persons needing special diets are announced by the Ministry of Food.

In future children holding the green ration book R.B.2, who qualify for extra milk under Classes I and II of the schedule of conditions set out in the Ministry's booklet MED. 2, will receive a total weekly supply of 14 pints of liquid milk. The certificate will be valid for a period varying according to the category in which the patient is included.

Mothers who are partly breast-feeding their infants under the age of 12 months and who have surrendered the infants' liquid milk allowance in order to obtain National Dried Milk may receive an extra 2½ pints of liquid milk a week for their own consumption on submitting to the local food office a medical certificate requesting this extra allowance. The grant will be for four weeks only and will not be renewable.

Persons suffering from diabetic ketosis will be granted three sugar rations a week on the same lines as diabetics with other intercurrent illnesses. The meat, fats, cheese, and bacon rations will be cancelled during the period when extra sugar is allowed. This arrangement will be for one week upon submission of a medical certificate at the food office and will be renewable on submission of further weekly medical certificates. One extra soap ration a week is to be allowed in cases of ileostomy under Class IIa of the schedule of conditions (MED. 2) qualifying for extra allowances of soap.

NUFFIELD MEDICAL FELLOWSHIPS

The Nuffield Foundation is prepared to award a limited number of fellowships to men and women who wish to qualify for senior teaching and research posts in social medicine, child health, industrial health, and psychiatry in the United Kingdom. Candidates must hold a university degree in medicine registrable in the United Kingdom, and will be expected to have had some general clinical experience since registration. Their talents and personal inclinations should afford good promise of their ability to advance knowledge and education in the branches of medicine named.

Normally the annual value of a fellowship will be between £500 and £800, according to the needs of the recipient. Travelling expenses will be paid to a Fellow who goes abroad for study. A fellowship will be awarded for one or more years, but, save in exceptional cases, will not be tenable for longer than three years. Applications will be received at any time. *Medical officers at present serving with the armed and auxiliary Forces of the Crown may apply now for fellowship tenable on their demobilization from such Forces.* Full particulars and application forms may be obtained from the Secretary of the Nuffield Foundation, 12–13, Mecklenburgh Square, London, W.C.1.

H. J. Bell (*J. R.A.M.C.*, 1945, **84**, 21) describes the unusually severe type of gonorrhoea met with among British troops in Italy. The disease was resistant to sulphonamides to a degree hitherto unknown.

Reports of Societies

EYESIGHT OF INDUSTRIAL WORKERS

Opening a discussion of ophthalmological problems and visual standards in industry at a meeting on March 24 of the Association of Industrial Medical Officers Dr. W. **Jeaffreson Lloyd** said that, in general, industry had not given enough attention to lighting, and legislation had not been bold enough. Even where there was good lighting there was no provision for maintaining its efficiency. He believed that eye protection was largely a matter for the safety officer. But he had noted that eye accidents occurred in batches and not continuously. Mr. **Joseph Minton** said there was no unified accepted system of visual standards in industry and no universal practice of examining new entrants. Compulsory medical examination of all workers could not be instituted at present because it would only create a pool of physically unfit requiring some form of direction. It was hoped that the direction of the workers into jobs for which they were physically best fitted would in future be combined with the training of the physically handicapped. Examining surgeons should be instructed about the visual standards required in the different branches of industry. People with all grades of vision and even the totally blind could be employed to-day. He suggested five visual groups for workers, and explained the type of work suitable for each. Examination of ocular muscle balance and binocular vision was necessary in men and women engaged in close work, which could be done by myopes with good vision in each eye; there was no evidence that such work had any effect on the rate of increase of myopia. One-eyed persons could be employed in most jobs, but the safety of the good eye should always be ensured. Further advances in industrial ophthalmology could be achieved only through close co-operation between the industrial medical service and the ophthalmologist. Mr. T. C. **Summers** said that from the point of view of the ophthalmic surgeon examination must be done under a mydriatic. It was remarkable how many people suffered from astigmatism. Every type of eye disease had been discovered on routine examination of industrial workers. He strongly condemned the use of a spud for the removal of a foreign body from the eye. He had found that hypopyon ulcer sometimes occurred after a foreign body. Penicillin had no effect in this condition, which, however, cleared up quickly on the intravenous administration of 500 units of vitamin C. An invisible intra-ocular foreign body might be missed unless there was an x-ray examination. High myopes should not be put on "heavy" jobs, since there was danger of detachment of the retina. In his view lighting and colour schemes in factories were questions for the physiologist and physicist.

PHARYNGEAL DIVERTICULA

At a meeting of the Manchester Medical Society on April 4 Prof. **John Morley** read a paper on pharyngeal diverticula based on his series of 21 patients with posterior pharyngeal pouches, and two further cases complicated by squamous epithelioma arising in the pouch.

A pouch described by the late Sir Arthur Hurst as an anterior pharyngo-oesophageal pouch was shown to be merely barium lodged in the vallecula between the tongue and the epiglottis. With regard to the predisposing causes, the average age in the series under review was 60 at the time of operation, males outnumbering females by more than 2 to 1. The differential diagnosis from carcinoma of the oesophagus, fibrous stricture, and cardiospasm was discussed and the importance of radiological examination stressed. A case was described in which on x-ray examination a pouch filled with food was mistaken for an intrathoracic goitre.

Discussing the operative treatment Prof. Morley advocated the operation of primary excision of the pouch and suture of its neck in one stage as against the two-stage procedure, which was followed by a fistula in 50% of cases. In his 21 pouches, all treated by one-stage resection, there were no deaths; 16 patients healed by first intention, three developed severe fistulae, one a transient fistula, and two residual abscesses. Preliminary gastrostomy was only employed with large pouches in patients who appeared to be bad surgical risks.

Dr. F. DURAN-JORDA read a paper on some new histological facts concerning the gastro-intestinal mucosa. He described the existence of what appeared to be a flat epithelial layer at the top of the gastric and intestinal mucosae (stomach, intestines, appendix, colon, and also the gall-bladder), and the presence of this layer was supported by the finding of capillaries in it. This layer was also found in foetal stomachs and in several other mammalian stomachs. The layer was studied by the speaker's method of formalin vapour fixation. He touched briefly on the relation between this new layer and the histology of some lesions found in the stomach, intestines, and ulcerative colitis, illustrating each stage with coloured photomicrographs.

Correspondence

Social Study of Hospital Treatment

SIR,—The social study of hospital treatment reported by Dr. Malcolm Brown and Miss Freda Carling (April 7, p. 478) has, I think, yielded facts of great importance. It provides evidence that only about one-quarter of the patients admitted to the medical wards of a general hospial are cured, and only about one-half return to full-time employment. As the authors point out, for the majority of patients the stay in hospital was merely an episode—sometimes a relatively brief episode—in a protracted period of disability and treatment.

A question which naturally arises is, Can we achieve any better results by improving the organization of medical treatment? At present when a patient is admitted to hospital he is uprooted from his environment and displayed among a row of other patients in the ward, where he can be conveniently inspected, examined, and investigated. The chief aim is to discover a known pathological process, and the chief hope to be able to administer a specific remedy. This method has achieved good results, but apparently only in about a quarter of medical cases. Research has dug deeply and produced remarkable remedies, but has the time not come when the field of disease should be cultivated more widely?

The authors of this study have brought forward several reasons why the hospital staff should extend their observations on their patients to the post-hospital period. Seven per cent. of patients still needed hospital treatment one year later and were not getting it. In 9% the period of incapacity after discharge from hospital could have been shortened by closer hospital supervision.

One of the great benefits which I think would result from the universal provision of consultant and specialist services is that the specialist would more often see the patient in his own home in the earlier stages of disease and in the company of the general practitioner. It would also be valuable, I think, for the specialist to make a similar visit after his patient's discharge from hospital. In this way the modern hospital with its highly organized resources for scientific investigation and treatment would be able to extend its influence in two directions: towards overcoming disease nearer its source, and towards the full reinstatement of the patient in useful employment. The patient would benefit from the earlier application of special methods and from a better follow-up after discharge from hospital. The specialist would benefit from being able more readily to study his patients, not simply as cases, but as living people striving to maintain the equilibrium of health in an environment too often overwhelmingly hostile.—I am, etc.,

Sheffield. JOHN PEMBERTON.

Civilian Mass Radiography

SIR,—Your leading article on this subject mentions the important matter of the "fate of the symptomless tuberculous lesion." You will be interested to learn that this is to form the Prophit Tuberculosis Survey of the Royal College of Physicians in a new scheme for research to be undertaken now that the original ten-year plan has come to an end. It is hoped that the new investigation will satisfy your advocacy that the method of mass radiography shall be "used scientifically," and that it will be an "efficient survey" despite your doubts about science and bureaucratic methods, which seem a little irrelevant. It is hoped that the Prophit scholars will work closely with the medical officers of selected mass radiography units as they have in the past ten years with a large number of medical officers of hospitals and other institutions.—We are, etc.,

C. E. NEWMAN,
Chairman,
ALAN MONCRIEFF,
Secretary,
Royal College of Physicians of London. Prophit Research Committee.

SIR,—Your leading article (April 14, p. 521) will help to focus medical opinion upon a new approach to chest diagnosis which has passed the experimental stage but which needs to be wisely applied if civilian requirements are to be satisfactorily met. The recent excellent report by a team working on behalf of the Medical Research Council illustrates the difficulties of a unit working in isolation and unrelated to any existing diagnostic chest centre. As is pointed out in your article, it is impossible as a result of one radiograph and one interview to determine the presence or absence of active disease. The decision to distribute the sets to councils of counties and county boroughs, which, under the general guidance of the Ministry of Health, are responsible for the diagnosis and treatment of tuberculosis, provides them with a permanent basis for future operations. Mass radiography thus becomes a branch of the tuberculosis dispensary activities and a diagnostic outpost. The medical officer in charge of the unit should be a member of the dispensary staff and take an active part in the reading of skiagrams and the assessment of clinical activity. This is so in Lancashire. In a county area it would be impossible for a mass miniature radiography unit to follow up the observation cases it finds—another reason why the unit is interlocked with the existing dispensary system.

It is perhaps not generally realized that the methods appropriate for conducting mass radiography of Service personnel are not necessarily the best for the civilian population. In the one case the following up of suspects is necessarily done by the same medical staff of which the mass radiography team forms part, because the suspects remain in the Services. But in the case of civilians the appropriate method appears to be for the mass radiography team to concentrate on finding the suspects, leaving it to the existing chest clinics to arrange for detailed diagnosis and treatment.—I am, etc.,

G. LISSANT COX,
Preston. Central Tuberculosis Officer, Lancashire County Council.

Rehabilitation and Cutaneous Diseases

SIR,—May I be allowed space in your columns to refer briefly to the rehabilitation of patients suffering from skin diseases. In recent years this matter has been taken up with interest by the Red Cross and St. John War Organization in co-operation with the War Office. A rehabilitation centre for Service patients suffering from these maladies was opened at the Auxiliary Hospital (B.R.C.S. and O.St.J.), Ragley Hall, during April, 1943, and the work done there has been so successful that a similar centre is being organized at the Auxiliary Hospital (B.R.C.S. and O.St.J.) at Greenstead Hall.

Rehabilitation has been defined recently as a "planned method of treatment designed progressively to mobilize all the available resources of the patient with a view to obtaining his most complete adjustment to social and economic needs." If this definition is accepted it follows that this method of therapy should be made available equally for the dermatological patient as for his more fortunate brother, who, either by sustaining a fracture or by some other means, becomes of interest to the orthopaedic surgeon. There is, however, more in the planned and careful rehabilitation of patients suffering from skin diseases than merely assuaging the demands of the social conscience of the community, for proper methods of rehabilitation can save man-power and should be of considerable interest to those concerned with industrial problems.

Our experience has shown that careful selection of the cases sent for rehabilitation is necessary, because this form of treatment is not a panacea and care must always be taken to prevent a dermatological rehabilitation centre from being used as a "dumping ground" for incurable cases. Many patients suffering from eczema, dermatitis medicamentosa, post-scabietic eruptions, dermatitis of the legs after trauma, recurrent impetigo, and seborrhoeic dermatitis do well, but often little benefit accrues in persons suffering from diseases such as psoriasis, who at first sight might have been thought very suitable for rehabilitation. We have, of course, every hope that as our knowledge and experience increase, problems which are now baffling will be solved, and that eventually we shall discover satisfactory methods of handling various diseases which at present defy our endeavours.

Major E. Miller, R.A.M.C., in a long and important paper on the psychiatric aspects of rehabilitation (*J. R.A.M.C.*, 1945, **84**, 54) has emphasized that many of the methods of therapy applied to human diseases are rituals and arouse in patients unconscious enthusiasms or hostilities. Also he has emphasized the importance of obtaining the co-operation of the patients so that they realize that they are being won (or weaned?) from treatment to vocational activity and thence to work and eventually to earning power. Unfortunately a minority of patients are consciously or subconsciously hostile to rehabilitation. Either deliberately or subconsciously they exploit their cutaneous maladies as mechanisms of escape from duties or avocations which they regard as hazardous or unpleasant or uncongenial. Obviously such persons present very great difficulties to those who attempt to rehabilitate them.

Major Miller, who has studied our problems at Ragley Hall, has stated that the psychological factors which influence rehabilitation are: (1) The level of the patient's intelligence and his aptitude for training (this aptitude is necessarily correlated with the intelligence level). (2) The personality of the patient. (3) The patient's ability to adjust himself to any new social and economic setting necessitated by the nature of his disability. (4) The extent to which a patient can build a new edifice of craft skill above the level of the base-line of his former occupation. Many accept this summary, and they agree that psychiatrists may give great assistance not only in helping to decide which cases should be sent for rehabilitation but also during the patient's residence at the centre.

It is hoped that an account of the work at Ragley Hall will soon be published. My present purpose will be served if I have brought to the notice of those interested in this subject the fact that we have accumulated evidence which I believe to be sufficient to indicate that the rehabilitation of patients suffering from skin diseases is a proper field of endeavour, one in which co-operation between the dermatologist and the psychiatrist is essential, and one which those interested in occupational dermatoses and similar industrial problems might profitably consider.—I am, etc.,

War Office, London, S.W.1. R. M. B. MACKENNA.

Nomenclature in Diphtheria

SIR,—In the *Journal* of May 6, 1944 (p. 626), there appeared an annotation under the heading of "Misleading Names," in which the "gravis," "mitis," and "intermedius" types of the diphtheria bacillus first described as such by my colleagues (J. S. Anderson, K. E. Cooper, F. C. Happold, and J. G. Thomson) and myself were considered. Much of the text of this annotation seemed to me to be sound, but I thought it was unfortunate that a heading "Misleading Names" should have been adopted, for there are a considerable number of rather hasty readers who will not go much further than string together the title with the names "gravis," etc., and will, in fact, have been misled.

As you quoted a review on the subject in which I had collected all the relevant evidence that I could find, I did not think that much would be gained by writing to you further on the subject at that time. You also quoted, however, an article by Frobisher (1943) published subsequent to my review, in which the general conception that the "gravis" strains played a predominant role in severe outbreaks of diphtheria was extensively criticized. Any suggested nomenclature based on observations of this kind must ultimately stand or fall by its merits. You will agree, however, that it is necessary to consider all the facts. What Frobisher has failed to realize is that it is not easy for him to appreciate a phenomenon of which he has had no experience. It is clear from his review of the observations on typing of diphtheria strains in the U.S.A. that "gravis-like" strains have only amounted to about 8% of all strains typed, and that what may be described as typical "gravis" to less than 2%. On that background the only epidemic of severe diphtheria which he mentions is a small one at Belair, Maryland, in which there was a mixed "mitis" and streptococcal infection.

In this review Frobisher also refers to the only recent outbreak of severe diphtheria in the Western Hemisphere which at all corresponded to those experienced in Europe in the last two decades—that at Halifax, Nova Scotia. He does not mention, however, that this outbreak was stated to be due to the "gravis" type of diphtheria bacillus, although that had a very close bearing on his general argument. It is true that the bacteriological details in the earlier reports of this outbreak were scanty and he may have considered that this point was in doubt. It seemed to me, therefore, that exact information about it was desirable, but difficulties in obtaining this information due to movements of personnel under war conditions have caused considerable delay.

The actual findings in this outbreak I have obtained partly from publications (Campbell, 1941; Morton, 1941; and Wheeler and Morton, 1942) and partly owing to the kindness of Dr. G. D. W. Cameron, who sent me a collection of strains and put some unpublished figures at my disposal. These strains were classified without any difficulty as "mitis," "intermedius," and "gravis" types and there was complete agreement between the Canadian results of Dr. E. T. Bynoe and my own, showing that in the period 1943–4, after the peak of the epidemic, about 65% of "gravis" infection persisted. Observations on strains put aside in 1940 (Dr. Cameron's information) indicated a higher percentage of "gravis"—i.e., in all respects the bacteriology of this epidemic corresponded to that seen in similar epidemics in this country. In another "gravis" epidemic recorded recently in England, that described by Grant (1945) at Gateshead, 81% of "gravis" strains were found in the investigation of 158 cases in the period 1941–3.

There are some interesting points of contrast and of similarity between these two epidemics. In both cases a very marked rise in the incidence of diphtheria and in the total diphtheria deaths was recorded in association with the presence of *C. diphtheriae gravis* as the predominant strain. In Halifax (Nova Scotia), where the population was about 60% immunized, it was mainly a disease of adolescents and adults, the case mortality remained low—about 3.7%—incidence of paralysis was low, and the immunized were little affected. In Gateshead, where extensive prophylactic inoculation was only adopted after the epidemic had manifested itself, the case mortality was high except among the fully immunized, paralysis was very frequent, and the incidence of diphtheria among the immunized was disappointingly high—not even Schick-negative nurses in the fever hospital were spared.

A third quarter from which additional evidence has come recently is Denmark, where Örskov, Andersen, and Poulsen (1944) draw attention to the appearance of "gravis" infection during the latter years of the war, in contrast to its previous absence (Tarnowski, 1942). The first-named authors mention some epidemics of "gravis" infection of unwonted severity, although no statistics of association of type and severity of disease on a big scale have been published since the appearance of "gravis" in that area. It is interesting to note that the appearance of "gravis" infection in Scandinavia has coincided with a remarkable increase of diphtheria.

I would submit, therefore, that although the suggestion that a patient infected with a "mitis" strain of diphtheria will necessarily have a mild illness is a misleading one, it is not a suggestion that has ever been made from this laboratory. The suggestion originally made was that the type of *C. diphtheriae* which we described as "gravis" would probably be found to be responsible for severe epidemic diphtheria. I believe that this suggestion has been justified by all the evidence that has since accumulated on the subject. That there should be immunological races within the "gravis" group and epidemics of varying severity associated with strains of different grades of virulence is in keeping with all experience of infective bacterial disease. And as is suggested by the observations described in Grant's paper, an epidemic will be followed by a period in which "gravis" will be widespread in the community but much less formidable owing to the presence of a large percentage of naturally immunized persons.—I am, etc.,

J. W. McLeod.

Infant Deaths

Sir,—Dr. S. H. Waddy's belief (April 14, p. 529) that wrapping babies has accounted for the deaths of thousands in the past few years cannot be allowed to pass without protest, the more so because, on his own allowance, it is not based on proper investigation or valid proof. The worth of his opinion can be assessed by his colleagues, but when it is published under bold headlines, "Wrapping up Baby is Bad," in the *Daily Sketch* the opinion becomes most mischievous.

Swaddling has been a universal custom from time immemorial. Its aim is to ensure the rest which is one of the essential needs of early animal life. Many letters in recent issues have attributed lack of breast milk to some defect or other in the lactiferous apparatus, but in the majority of instances mismanagement in the feeding is at fault. To whom must we assign the blame? Regretfully we must admit that neither nurse nor doctor can always be acquitted.

Let us look at things from the start. The baby born and mother resting, the tired doctor leaves for home and the baby is not put to the breast for probably some hours. I maintain that the infant should be put to the breast *immediately* after it has been washed. A lecture by Dr. Targett, published in the *British Medical Journal* some 42 or 43 years ago, insisted on this, for by it milk production is early encouraged and uterine contraction stimulated. He insisted that the doctor should not leave until the infant had been put to the breast; also that the mother should be allowed to manage her own baby with as little assistance from the nurse as possible. The baby, after its first attempts at sucking (and this applies to every subsequent feed), is comfortably wrapped in a soft shawl, laid in its cradle, and goes to sleep. If at any time during the first few weeks it is left with the arms free it throws the arms aimlessly about and jerks the legs, an expenditure of energy which should only be allowed for short periods for exercise before feeds. That eminent authority, Dr. Hector Cameron, insisted on swaddling, and advised what he aptly called insulation of the baby from a nervous mother by laying a soft pillow across her arms and so preventing her tremor from reaching the infant. Dr. Coldrey rightly observes that breast-feeding is an emotional business, and his succeeding remarks are much to the point, especially those referring to visitors; rest of mind is as important to a nursing mother as rest of body.

Over-tight bindings are, of course, harmful, but swaddling is not tight binding. A light knitted shawl, loosely wrapped around the upper arms and shoulders, restricts the exhausting waving of limbs but allows free respiration. This should remain a universal practice for the first few weeks of life. How, we may ask, did those bruised and shocked babies survive and thrive? Because the working classes always swaddle their babies and usually feed them without difficulty. Dr. Waddy's belief is false and mischievous; an arm-free baby is just as likely to wilt as an overtight one, while a swaddled babe will rest and thrive.—I am, etc.,

Berkhamsted. T. Blanchard Sellors.

Women in Labour

Sir,—In your issue of April 7 (p. 495) Dr. John Elam has inserted a provocative final paragraph in his letter which really cannot be allowed to pass without a mild protest. In spite of the risk of giving him a malicious pleasure in seeing a fish rise to his bait, one must query the number, and perhaps even the existence, of these "young women medical officers of health" who oppose the provision of safe methods of analgesia in labour. One was under the impression that it was an accepted proposition that a gas-and-air apparatus should be provided in all maternity hospitals; if the machines are not kept in working order, Dr. Elam's letter will serve a useful purpose.

But why blame the M.O.H., and the *women* medical officers of health at that? In municipal hospitals surely the medical superintendent is responsible, while in voluntary hospitals the inspection of apparatus by any M.O.H., male or female, would be rightly resented. Incidentally, very few young women, even in wartime, have risen to the position of medical officer of health, and I feel pretty sure that none of them would agree to Dr. Elam's classification of her sentiments.

Perhaps, however, Dr. Elam has misinterpreted the effects of those public health medical officers who endeavour by their teaching to the expectant mothers under their care to minimize the dread of the approaching confinement, and to give them that expectant curiosity and confidence which relax tension and greatly diminish, if they do not altogether remove, the pain of a confinement. The case reports of Dr. Dick Read show that for many women childbirth can be an amazing psychological experience associated with labour but with little pain. Tradition, however, insists on the presence of pain, and a recently delivered mother confided to me that she dared no longer mention that her labour was practically painless, as the reception of her story invariably met with the contempt of her listeners, who classed her either as a liar or as "abnormal."

It is easy to suggest the presence of pain, and the doctor who prepares his patient to "go through hell" will doubtless see a painful labour in a frightened woman, where there will be ample need for analgesics and anaesthetics. It should be maintained, however, that this is not the correct preventive attitude at the pre-natal clinic. This is shown rather by the exercise classes for expectant mothers, carried out to dance music and with a good social atmosphere, which are sponsored by the M.O.H. of Kensington. As the medical officer in charge, I am convinced that they have done a great deal to promote easy and quick confinements by helping relaxation and fostering a healthy attitude of confidence.

Looking back thirty years, I remember insisting that women should have an anaesthetic during delivery, in spite of their feeble pleas that they did not need it. In the light of experience, I think that that was just as reprehensible—or even more so—than denying an analgesic to the woman who asks for it. We must not suggest pain unnecessarily in what is actually a normal and physiological process, though we must certainly be prepared to relieve it when it occurs if it is in our power to do so. Civilization must not remove us too far from the normal. It surprises me, sometimes, that these kindly old gentlemen to whom Dr. Elam refers have not suggested an anaesthetic for the bride on her wedding night. Surely the removal of fears and inhibitions by appropriate educational methods is preferable to anaesthesia?—I am, etc.,

Kensington, W.8. Violet Russell.

Sir,—I fully endorse all that Dr. John Elam says in his letter about the unsatisfactory administration of gas-and-air analgesia in labour. Much to my sorrow I have found his words only too true. I write not to enlarge upon the fact but to suggest what can be done about it. It seems to me that the solution to the problem mainly lies in the improvement in teaching arrangements—e.g.: (1) Throughout the country there should be a standardized curriculum for the special instruction in the essentials of obstetrical analgesia which is received by the midwife. (2) The lecturer-examiners should themselves have intimate knowledge and experience of the subject, and only such should be approved by the Central Midwives Board. (3) The Central Midwives Board, and not the individual hospital, should grant the certificate to the midwife after she is successful in the examination.

By obtaining this reorganization of the regulations under which midwives are trained in the use of gas-and-air analgesia a beginning at least would be made in raising the status and value of the qualification.—I am, etc.,

Liverpool. R. J. Minnitt.

Sir,—The letter from Dr. John Elam is pertinent and timely, but disappointing in that the criticism is mainly destructive. This is easy; so many have thought along these lines for so long. The problem is, How can we *achieve* "triumph over pain" for all women in labour? Not, I feel certain, from the utmost support of the "old and elderly male county councillors" quoted by your correspondent; neither is the cause to be prejudiced by the alleged opposition of "young women medical officers of health." These latter are in no position—by virtue of either specialized training or professional influence—adequately to help or materially to hinder.

While I have much interest in and every sympathy with the theme of Dr. Elam's letter, I cannot refrain from suggesting that the problem should be divorced from everything in the nature of cheap sentiment and submitted to the cold judgment of reason and fair play. It would appear that with advancing civilization and concomitant changes in mode of life, the human threshold of pain is accordingly lowered. While a painless labour is by no means a thing unknown, yet for the average parturient woman of to-day labour, if unrelieved, may be considered to represent hours of sheer agony. Why is it, then, that so many of our women are permitted to remain the defenceless victims of the primeval curse? Not from any so-called religious bias; even the most retrograde dare not use that argument to-day. What, then, are the circumstances responsible for a condition of affairs which, as Dr. Elam in no overstatement says, "must make us utterly ashamed of our national maternity services"?

As I see it, there are two main reasons. First, women, being women, put up with it and go on having babies. If the last supreme act in the propagation of the species had fallen to the lot of man instead of woman the problem in question would not now have arisen; our profession, predominantly male, must have seriously tackled it long ere this. So, in the first instance, women are themselves to blame for not demanding that degree of relief from suffering which can be theirs with perfect safety. Demand ultimately creates supply.

The second and more serious indictment is directly against our profession. How many of our number who undertake the care of an expectant mother have taken the trouble to make themselves thoroughly conversant with all the analgesic techniques at our command to-day? In the absence of this knowledge the unfortunate patient is told: "No, it wouldn't be safe for the baby." And thereafter the mothers, as mothers are made, is prepared to "go down to hell," as a mother of three has said to me. This self-admitted incompetence of the accoucheur—as incompetence only it can be called—is responsible for a large proportion of the needless suffering of women in childbirth. Again, many of our women are confined in voluntary and municipal hospitals. How many of these have an anaesthetist on the resident or consultant staff to direct and control this admittedly important aspect of a hospital's work? For the most part it would appear that the analgesia and anaesthesia in these institutions may be left to the inexperience of a junior resident, or, in the case of the more serious emergency, to the good nature of a skilled outsider who hesitates to refuse an urgent call. This in 1945, a century after Simpson established a place for anaesthesia in labour for all time!

To scatter numerous pieces of even properly functioning apparatus throughout the labour units of our hospitals is no answer to the problem; there is no universal analgesic which will meet every case. Each patient must be considered with regard to her psychological make-up, parity, type of labour to be expected in relation to the obstetrical findings and the surroundings in which she is being confined; only then can the most suitable method of sedation be decided upon. For this to be universally available the present-day number of skilled personnel will require to be considerably augmented, and the best results obtainable can only be achieved by the closest co-operation between enlightened obstetricians and experienced anaesthetists working together, each appreciating the why and wherefore of the other's aims and difficulties. In short, the obstetrician must possess a certain minimal knowledge of pharmacology, and the anaesthetist something more than a smattering of the art of obstetrics.—I am, etc.,

Belfast. Florence M. McClelland.

Sir,—I am in complete agreement with all that is said by Dr. John Elam in his letter on women in labour (April 7, p. 495). I speak as a doctor and a mother, and can only say that it is my most sincere hope that when my baby is older I shall be able to obtain a resident obstetric post and do all in my power to alleviate the sufferings of the women in labour.

One of the difficulties seems to be that the majority of people who attend women in labour—students, nurses, and women doctors—have no personal experience of labour pains and seem to imagine the women are "making a fuss." There is no need to be sentimental, but there is to be humane. Busy obstetricians tend to see their patients early in the first stage and, if things are going well, reappear only when it is almost time to deliver the head. There are many hours of pain between, and the nurse in charge has often neither the knowledge nor the desire to mitigate the suffering.

We are always hearing about the falling birth rate; let us therefore see that everything possible is done to help those who are willing and eager to have children if only they could feel certain that when their time came they would receive efficient analgesia. We do not expect labour to be without suffering, but much can be done to help.—I am, etc.,

"Mother and Doctor."

Treatment of Vaginal Discharge

Sir,—Mr. Oswald Lloyd (April 14, p. 509) does well to stress the eternal vigilance and persistent patience necessary to treat pathological vaginal discharge. But what of the aetiology? On close questioning there can be little doubt that the greatly increased incidence and recurrence of these mixed infections, especially the trichomonas, are due to the regrettable use of occlusive rubber caps, and even tampons, which are commonly well smeared with lingual saliva before introduction by dirty fingers.

Hitherto the treatment has been long and tedious, but bearing the above fact in mind, from the point of view of advice we have of recent years found a cheap, quick, and almost specific way of dealing with these fretful patients—namely, the insertion of a 2-drachm vaginal pessary made up with a glycogelatin base containing 30 gr. each of sulphathiazole and zinc peroxide. In the case of virgins and infants the size and dosage can be halved or quartered. If there is any idiosyncrasy to the sulpha drugs, 1 gr. of proflavine is substituted. These pessaries are inserted on six alternate nights and the patient is douched or douches the following mornings with a normal saline or a 0.5% solution of lactic acid. Where possible the vagina is blued out with a 2% of gentian violet three days before the simple treatment is begun. In the case of adolescents (not menopausal patients) we do not now prescribe stilboestrol, as we have found the disturbance in the menstrual rhythm to cause anxiety and draw unhealthy attention to the pelvis, but if cases are refractory or tiresome we have prescribed menformon vaginal pessaries on the six alternate nights or for ten days after cessation of all treatment. In a follow-up of a very large number of hospital and private patients continuance or recurrence of the discharge has been exceedingly rare, and should either occur we have found that the patients at once reacted to a few days' repetition of the treatment.—I am, etc.,

London, W.1. V. B. Green-Armytage.

Repair of the Oblique Hernia

Sir,—Mr. F. R. Brown, by his recent letter (April 14, p. 532), has stimulated me to comment upon three of his remarks. Two concern extracts quoted by him from an article by myself in the *British Journal of Surgery* (1945, **32**, 381).

In regard to post-operative pain in the thigh following removal of strips of fascia lata, whether by fasciotome or open operation, it is correct that 25% of my series of 128 Gallie repairs experienced this complication. In assessing the pain significance for morbidity statistics I included every single patient who complained of pain in the affected thigh, though frequently it passed away within a few days. In only a few did it persist for longer than a month or six weeks, and there the subjects were either members of the Services and not anxious to return to duty or civilians anticipating compensation. In none was the pain so severe that the patient desired any active treatment, such as operation for repair of muscle hernia.

The risk of penetrating the femoral vein with a Gallie needle may not be great, but the accident has occurred, and did so in the experience of a colleague. It has also been mentioned several times in the literature, and is, in fact, a recognized danger associated with the use of a Gallie needle. Such accidents do happen in the best-regulated circles, and need not be a reflection upon the general competence of the surgeon concerned. Doubtless Mr. Brown has also had his surgical mishaps. If he has not he can hardly have done very much surgery, and so I feel that his last phrase is possibly a little severe on those who have been less fortunate than himself in this respect. I might mention in passing that the case "which came to my notice" where penetration of the femoral vein ended in death did not occur in my own personal practice.

I noticed that Mr. Brown referred as "my method" to the principle of using strips of material cut from the sac as a substitute for fascia in repair of large scrotal herniae, umbilical and ventral. It may be the method he generally uses, but the principle is old, and has been mentioned in papers in American journals on several occasions. I have one reference to hand at the moment published in 1925: Babcock, *Surg. Gynec. Obstet.*, 1925, **40**, 853. I think I have also seen the method described as far back as 1912, but I cannot give the exact reference as I had no need to note it for my own purposes. Possibly some reader may be able to give the earliest report.

I have no personal experience of the operation described by Mr. Brown and Mr. James Riley (March 17, p. 386), but it would appear to offer several advantages over fascia lata strips. It would be interesting to have the recurrence figures for several series of cases.—I am, etc.,

Aberdeen. GEORGE B. MAIR.

Imbalance of Vitamin B Factors

SIR,—Miss Marion Richards's experimental work on rats (March 31, p. 433) shows that excess of one factor of the B vitamin group (aneurin) may easily precipitate a masked deficiency of another (pyridoxine), thus demonstrating the interdependence of the single factors. It is important to realize that latent deficiencies may be made manifest by doses of vitamin B_1 far less than those Miss Richards refers to both in animal experiments and from the literature of clinical cases (e.g., 220,000 i.u. in 3 weeks). This point is illustrated by the following recent case.

A woman of 54 was seen in consultation at a country hospital. She had a large haematemesis some 2 months previously and was kept on a strict ulcer diet mainly consisting of milky foods and glucose water. During the last 2 to 3 weeks she had become jaundiced. On examination: cachexia, smooth-edged enlarged liver reaching the umbilicus, palpable spleen, distended abdomen with considerable ascites, oedema. The tongue was magenta red, smooth, shiny, and atrophied; the mucous membrane of the entire oral cavity was inflamed and showed extensive petechial bleeding. A diagnosis of liver cirrhosis was suggested, and a protein plus carbohydrate-rich diet was advised and in addition daily intravenous injections of 5 mg. aneurin, 10 mg. riboflavin, 100 mg. nicotinic acid and ascorbic acid, and 10 mg. vitamin K. Two days later the anorexia, dysphagia, and general condition were considerably improved, but the patient had developed a very painful angular stomatitis with deep cracks. It was then found that ampoules of riboflavin and nicotinic acid had not been available locally and therefore had not been given. The precipitation of a previously latent riboflavin deficiency caused by the sudden administration of vitamin B_1 was suggested, and the angular stomatitis disappeared completely within a few days as soon as riboflavin and nicotinic acid were procured and given to the patient.—I am, etc.,

London, W.1. Z. A. LEITNER.

The Prisoner-of-War Mentality

SIR,—I wrote to you about a year ago from India, where I was serving, on the question of the future of our men in enemy hands (April 22, 1944, p. 568). I have not been in a position to follow all of the correspondence, but I notice that not once have I been correctly quoted.

I confess to being surprised at the assumption of most of the writers that the problem would be altogether a "psychological" one. The word was never used by me. I wrote of conditions as experienced by the men, and not the officers. The camp at Lamsdorf in the last war, where I was a prisoner with other soldiers, has been recently in the news. Those of us who survived are well aware of what being a prisoner in German hands means. Has he changed for the better? Recent newspaper reports and broadcasts have described the conditions of some of our men. There are still many in Japanese hands. Acrimonious correspondence can serve no good purpose, and my plea was for recognition of what these men have suffered, for care by men skilled in the treatment of malnutrition, amoebic dysentery, and similar disease; the recognition of disability, and, for them, a measure of financial security.

Starvation and disease are not all the story. There is something else, but I am not interested in the term "neurosis" as applied to it. Again—I never used it. Whatever it is, some of us think we know how long the effect of prisoner-of-war experience lasts. I would point out that having served in the ranks of a line regiment in the last war and as an officer in the R.A.M.C. in this, I am well aware of the courage and spirit of our men.—I am, etc.,

Edinburgh. JOHN HARKNESS.

Problems of Industrial Ophthalmology

SIR,—The Institute of Ophthalmology proposes to devote a considerable proportion of its funds to industrial ophthalmology. In view of the absence of any co-ordinated work in this field it is felt that a national survey of workers and of work already accomplished is a necessary preliminary to the undertaking of research on any specific aspect of this very extensive subject. The Institute therefore asks all who have routine experience in any branch of industrial ophthalmology, or who have undertaken original work bearing upon it, to communicate with the Institute stating briefly their experience and defining the aspect of the work with which they are most familiar—medical supervision, safety, lighting, industrial psychology, etc. It is the Institute's policy to promote the investigation of industrial ophthalmic problems in the districts in which they arise. It is hoped that those replying to this request will be willing to co-operate in their own areas and in their special fields of interest and experience as the national scheme develops.

This invitation is extended not only to individual workers but also to research and other organizations concerned. The funds will be distributed on the recommendation of the Scientific Executive Committee in the form of grants for approved work. The committee proposes, initially, to support, co-ordinate, and publish work undertaken throughout the country.—I am, etc.,

P. T. ETHERTON, Colonel,
Secretary, Institute of Ophthalmology.

Royal Eye Hospital,
St. George's Circus, S.E.1.

Shall We Nationalize Medicine?

SIR,—Some socio-psychological aspects of the much-debated question of the nationalization of medical practice may help to clear the air and define the conflicting outlooks. In general, all men are taken up a good deal with the consideration of achieving a greater freedom. Apart from the factual limits to freedom, men are apt to overlook the point that they themselves limit their own freedom in the comparative compulsion and insatiability of their own strongly developed character drives.

In a previous generation personal success was made a somewhat exaggerated god, and men were led to believe that if they worked hard enough and long enough "off their own bats" they could achieve any success. This entailed gaining a freedom of a sort, a rather lonely and shaky freedom, relying for its strength on power, riches, or intellectual attainments, but one which, in the ideals of medical service, a general practitioner could readily strive for, and, in the liking and confidence of his practice, fairly securely gain. To the degree that he was a good judge of human nature and a sound amateur psychotherapist, as well as having a sufficient knowledge of the mechanics of pathology and pharmacology, he achieved his end, but towards that end tended to become an ardent and perhaps over-developed individualist.

A different kind of freedom can be gained by a limiting of individual judgment and responsibility, in acting faithfully and fully in following out prescribed rules and regulations which in a broad estimate are *pro bono publico*. In this direction a man's character tends to harden and over-develop towards a blind and explicit conforming to regulations—"rules for rules' sake"—his end being the safety and security of (presumably) beneficient mass action and mass strength. Up to the introduction of National Health Insurance doctors and civil servants lived and strove in worlds apart, but, in common with all divisions of society, have since become more and more in and of each other's sphere, and afraid of and intolerant of what *can* be each other's destructive (rather than constructive) peculiarities. As medical practice has been, is, and must continue to be, a predominantly psychotherapeutic relationship between doctor and patient, in which much medicine and attention are given or withheld on empiric grounds, an understanding recognition and division of what is the especial function of therapist and regulationist will have to be defined, and each side granted what *can* be the *best* activity in the *total* relationship to the community.

All psychotherapy, amateur or other, depends on the confidence or *rapport* between the parties concerned. This depends on at least a degree of liking and approval between them. This is fundamentally a matter of feeling, of emotion at its sincerest and truest, of warm- and open-heartedness. A doctor who does not like his patient to some extent, and vice versa, will do him little good, except in a purely mechanical way, this comprising, at a guess from ten years of general practice, two-fifths of the process of "curing" the patient. In the, what one might term, over-developed civil-servant view there is no place for feeling, and conduct is entirely right or wrong, just or unjust, what is legally due or not due, as in a court of law. Thus the over-developed (and such over-development is often largely unconscious to the personality of which it is a part) individualist and "ruler for rules' sake" are bound to clash and to be inordinately afraid of surrendering their own particular concept of liberty to the possibly over-insistent demands of the other for his "rights."

It would seem that whatever stand a doctor might wish to take inside or outside a national service, a compromise of attitude *must* be granted by each side of the equation to the other's status and especial utility within the framework of the general advancement of health—a word really meaning "wholth," a wholeness of mind and body, and thus a potentiality for expansion of happiness (a matter and aim practically unknown nowadays) and for a growth to a mutually enlarging service.—I am, etc.,

Morpeth. L. F. Donnan.

Sir,—In his letter concerning a 100% service, I presume that Dr. Thornton (April 14, p. 533) is really advocating a 90% national service and a 10% exclusively private service. He suggests that each should be on its mettle and vie in friendly rivalry with the other. This would be ideal. The only rough test as to the success of such rivalry would be whether one gained in popularity at the expense of the other. But if those patients in the 10% group were precluded, except by the unlikely method of a voluntary reduction of income below an arbitrarily fixed level, from moving into the 90% group, while all those who wished, subject to personal economic restraints, were free to move from the 90% into the 10% group, there could be no fair test. The only fair condition for such a test would be to make the national service available to everyone, and to safeguard the freedom to use or not to use it for everyone.

Two other advantages would accrue. Those doctors—and they are among our best—who now attend almost exclusively the 10% would have, in so far as they are potentially affected, a greater incentive to make certain that the service should be the best possible in its administrative structure and in its medical and financial standards. Those patients among the 10%, proportionately the most influential, who sought to make use of the service would have an added incentive to insist that the service should be the best possible, particularly in regard to its amenities.

I am all for friendly rivalry and essential freedom, but they must be fair.—I am, etc.,

London, N.2. G. W. M. Mackay.

Sir,—Dr. H. Dakin (April 14, p. 535) voices what I believe to be the real opinion of the majority of the profession. "Free choice of doctor," yes, within regular hours. If a patient needs a doctor in the night he needs *a* doctor, and *a* doctor we should see that he gets; but whether that doctor is to have the patient's favourite shade of hair, eyes, etc., is another matter. Now is our chance to make the future conditions of the general practitioner reasonable. We must no longer unnecessarily be on duty for 24 hours every day. If we are to be servants of the State, whether on the lines of a 100% panel system or otherwise, we must insist on a rota of duty, even though a modified one—e.g., one doctor in seven available for evening and night visits once a week.

The representatives of the medical profession must not lead us into a complete slavery based upon an ideal of personal service, which originated as a result of the unavoidable individualism of an earlier age. I am not a Socialist.—Yours, etc.,

London, S.W.2. M. C. Breese.

Sir,—Dr. H. Dakin (April 14, p. 535) endeavours to set out the advantages to the medical profession of a national service, it being his cynical conclusion that if only the profession could be made to believe that it was "on to a good thing" such a service would be immediately acclaimed by all. What is this Utopia that he contemplates? A 9 a.m. to 6 p.m. working day with a rota for emergencies over the rest of the 24 hours; freedom from the tyranny of telephone and door-bell in the home; relief from monetary worries when setting up in practice, during illness, and on retirement.

Let us examine this question of a set-hour working day from the doctor's point of view. (The disadvantages to the patient are only too obvious, and, indeed, are tacitly admitted by Dr. Dakin, though, strangely, he fails to express them as such.) The practice of medicine is an art as well as a science, and for its best performance demands some of the freedom that is accorded to the artist. Most of us prefer to arrange our day so as to do things in our own time and our own way, not working within prescribed hours. Happily few doctors have the "9 a.m. to 6 p.m. and then down tools and leave it to the next shift" mentality. The introduction of a national service is not the only remedy for the tyranny of telephone and door-bell and would merely substitute the tyranny of red tape and "forms"; the tyranny of "control"; the tyranny of being a cog in a Civil Service machine.

As for Dr. Dakin's third point, with remuneration comparable to that of the present-day public health services, the doctor would in truth be in a sorry case if out of his pittance he had to provide for buying his practice, for possible illness, and for his pension. In any event under the present system it is not difficult to borrow capital for the purpose of buying a practice, and it is possible for the provident both to save and also to insure against the results of illness and old age—and this without that sacrifice of personal freedom and liberty which mean so much to those who look on the practice of medicine as something more than just a means of gaining a livelihood.—I am, etc.,

London, N.W.3. Helen Bower Alcock.

Hearing Aids

Sir,—Considerable interest has been aroused as a result of the press reports of the recent discussion in the House of Lords concerning cheaper hearing aids, and I should like to be allowed to record the following facts.

Four committees exist: (1) The National Institute for the Deaf Medical Committee (protection of the deaf public against inefficient aids and unethical suppliers). (2) Medical Research Council Electro-acoustic Research Committee (fundamental research into electro-acoustic problems). (3) British Standards Institution Committee (calibration and standardization of audiometers). This is quiescent at the moment. (4) The Hearing Aid Manufacturers Association Technical Committee, which is in three sections: (*a*) utility aid and general standardization; (*b*) audiometers and hearing tests; (*c*) technical education for the staff.

As president of the Hearing Aid Manufacturers Association I am privileged to attend meetings of the National Institute for the Deaf Medical Committee. The secretary of the National Institute for the Deaf attends most meetings of the Hearing Aid Manufacturers Association. The latter is now represented on the British Standards Institution Committee. There is as yet no official contact between the Medical Research Council Acoustic Committee and the Hearing Aid Manufacturers Association Technical Committee. The former committee is, however, fully informed of the work of the latter and closer co-operation may result.

Any hearing-aid manufacturer whose instruments meet with the approval of the National Institute for the Deaf Medical

Committee, and who agrees to give home trials of at least one week before selling an instrument, to avoid door-to-door touting and other undignified practices, is put on the list of the National Institute for the Deaf. It is a great pity that the general press has not given more publicity to the work of the National Institute for the Deaf, for many deaf persons are quite unaware of the existence of the approved list and its significance.

From 1934 to the outbreak of war the British hearing aid manufacturers, with the help of British valve makers, led the world in the design and production of pocket-valve amplifiers. British valve aids were exported to most foreign countries, and they were smaller and more efficient than anything available elsewhere. Since the war members of our association have had a tremendous struggle to keep their instruments in operation and to supply the users with adequate battery and other replacements. Encouraged by the National Institute for the Deaf we produced the specification of a "pooled" utility three-valve pocket aid, which we were hoping to manufacture during the war to sell at a price around £10. We have been unable to the present time, however, to obtain supplies of valves, components, and batteries over and above our existing very small allocation to make the manufacture of these utility aids possible.

As a result of the returns made to the Board of Trade it can be stated that the number of valve amplifier hearing aids in use in this country is under 50,000. The total figure of deaf people who could be helped by valve aids is undoubtedly higher, but it includes many who obstinately refuse to wear an aid. It is certain that among the potential users there are very few indeed who remain without an instrument because they cannot afford it. Before the war our members supplied robust and reliable valve aids at list prices from eight guineas, which operated on standard batteries with a maintenance cost amounting to only about sixpence per week. Hospital clinics help patients to obtain aids at substantially reduced prices, and many approved societies give grants towards purchase. Deaf ex-Service men are given aids free of charge by the Ministry of Pensions, with whom a number of our members have contracts. Happily this business is negligible: the number of men recommended for hearing aids last year was given officially as 60.

In view of the 100% purchase tax on leather containers for these instruments, the increased cost of labour, and the limited demand, together with the need for a fair margin for the distributor as well as an allowance for hospital discounts, it is doubtful whether an efficient instrument can be made available at a low price.—I am, etc.,

O. C. LEADBITTER,
President, Hearing Aid Manufacturers Association.

Carotinaemia in the Tropics

SIR,—Dr. E. Cochrane, whose note on carotinaemia in the Tropics appeared in the *Journal* of April 7 (p. 483), has possibly overlooked the part played in West African diets by red-palm oil. Most Europeans in W. Africa eat either "palm-oil chop" or "ground-nut chop" every Sunday, and possibly some do not cast out the excess carotene of the palm-oil so readily as others.

Several years ago, while working in a part of the Gold Coast where palatable and nourishing food was scarce, I fell back upon palm-oil soup almost every day. After a few weeks I noticed that although I felt well and vigorous my skin was orange-coloured, especially on the palms and soles; the whites of the eyes were unaffected. Red-palm oil was already known to biochemists as probably the richest source of carotene, and it at once occurred to me that the palm-oil carotene was responsible for the phenomenon. I therefore abstained from palm-oil and found that 2 to 3 weeks' abstinence restored a normal-coloured skin. On resuming the palm-oil diet the yellow colour returned and was again banished by abstinence. I derived some amusement from repeating this several times.—I am, etc.,

Edinburgh M. J. FIELD, B.Sc., Ph.D.

Treatment of Pediculosis Capitis

SIR,—Dr. Elizabeth Scobbie's article on the treatment of pediculosis capitis (March 24, p. 409) was of great interest. I have been trying D.D.T. also and have a small series of cases, with results in agreement with Dr. Scobbie's. D.D.T. powder was first tried in 5 patients with pediculosis capitis. It was found that the powder did not stay on the hair and the method was discarded as unsatisfactory. Similarly in 7 patients with pediculosis corporis dusting the powder on the underclothing had not killed the lice by the following day. The powder was then rubbed into the hairy parts. This was repeated in 2 to 3 days following a bath, and all patients were finally passed as cured after 3 weeks' observation. A 4% solution of D.D.T. powder in liquid paraffin was applied to the scalp with a stiff brush in 12 patients with head lice. Next day no living lice were found. The hair was washed and tooth-combed. Observations for 3 weeks showed all cases were cured. Benzyl benzoate emulsion with similar technique has given as good results in a large number of cases, but I have no doubt that if the tooth-combing cannot be relied upon to be carefully done then the D.D.T. solution, in view of its remaining layer on the scalp, is by far preferable. Whether ascabiol is an "easy method of freeing the scalp from nits" or not, my nurses are unanimous in stating that combing after benzyl benzoate emulsion takes much less time to remove all the nits than after D.D.T. in liquid paraffin.—I am, etc.,

Nottingham. A. D. FRAZER.

Organization of Research

SIR,—"Filching of intellectual work" and deliberate withholding of new ideas is put forward by Dr. G. Arbour Stephens (April 14, p. 535) as a bar to central organization of research. In psychiatry new ideas have always been and still are prolific: but although neurology has contributed so much to physiology that our knowledge of the working of the central nervous system is almost complete, little of physiological importance has emerged from psychiatry. The neglect of a proper physiological basis for psychiatrical research is in itself an indication of the great need for central organization.

Medical research should be ennobled as a profession. The reward for such research should be in doing it and not in the expectancy of later honours or rewards. The type of sporadic research solely for personal advancement or monetary benefit from patents will, I hope, disappear. As in the past, private research will always be attractive and occasionally useful to the community, but in future any real advances in the prevention and cure of disease (including mental disease) are only to be expected from the pooling of ideas and resources; the constitution of active and interested committees; the criticisms of everyone qualified to criticize; the help freely given by those possessing special knowledge and experience; and above all the patient investigation by competent workers of pertinent (though not necessarily minutely specified) problems urgently awaiting solution.

Should results be attained almost simultaneously by other workers, it should be a matter for rejoicing rather than dismay, so long as there are committees sharing the responsibility for the work and the expenditure of public money.—I am, etc.,

Birmingham. F. A. PICKWORTH.

Universities and Colleges

UNIVERSITY PARLIAMENTARY ELECTIONS

The Registration Officer of the University of Oxford has sent the following communication from the University Registry:

> Voting for University constituencies at Parliamentary elections is conducted by post, and voting papers are sent by each University Electoral Registration Officer to the last recorded address of every elector, unless such address has previously proved insufficient. In view of the impending general election I am writing on behalf of all University Registration Officers to urge every voter for a University constituency who has changed his address since registering as an elector and who has not notified the Electoral Registration Officer of his University of such change, to do so as soon as possible. Any elector who has reason to believe that his (or her) name or designation is not correctly recorded in the Register should also communicate with the Electoral Registration Officer of his University. There is little doubt that many electors have changed their addresses within recent years without notifying their University Registration Officers, and a wide response to this appeal would not only save many last-minute applications for voting papers but would help to ensure that those who have a right to receive voting papers receive them in time to record their votes.

UNIVERSITY OF GLASGOW

At a graduation ceremony on April 14 the following higher medical degrees were conferred:

M.D.—J. H. Stirrat (with commendation), A. A. Gilmour.
Bellahouston Medals for eminent merit in theses for the degree of M.D. were awarded to A. W. Kay and J. H. Lawson.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

A meeting of Fellows will be held at the College on Tuesday, May 1, at 3 p.m. A report on College affairs will be made and there will be a discussion on the present state of negotiations on the Government White Paper on "A National Health Service."

Obituary

SIR HUBERT BOND, K.B.E., M.D., F.R.C.P.

A long and distinguished career in the service of psychiatry closes with the death on April 18 of Sir Hubert Bond, who became a Commissioner of the Board of Control in 1914, and in 1930 was made a Senior Commissioner, retiring from that post on March 31, 1945.

Charles Hubert Bond was the elder son of the Rev. Alfred Bond, of Powick, Worcestershire, and brother of Surg. Vice-Admiral Sir Reginald Bond, who was Medical Director-General of the Navy and Honorary Physician to the King. He was born at Ogbourne St. George in Wiltshire in 1870, and educated privately and at Edinburgh University (where he was Mackenzie Bursar in 1889–91) and King's College, London. He qualified in medicine in 1892, taking the B.Sc. in public health in the following year, the M.D. of Edinburgh in 1895, and the D.Sc. in 1898. Choosing to specialize in mental diseases, a subject in which he was Gaskell gold medallist in 1897, he worked in turn on the medical staffs of Morningside (Edinburgh), Wakefield, and Banstead Mental Hospitals. In 1898 he was appointed deputy superintendent of Bexley Mental Hospital (London County Council), in 1903 first medical superintendent of the Ewell Colony for Epileptics, and in 1907 first medical superintendent of the London County Mental Hospital, Long Grove, where he remained until 1912. In that year he was made Commissioner in Lunacy, and in 1914 he became one of the Commissioners of the Board of Control which was set up under the new Act. In 1930 he was appointed one of the four Senior Commissioners who, with the chairman, constitute the Board.

[Press Portrait Bureau

With his commissionership Bond combined a great deal of lecturing, inspection of examinations, and administrative work. In 1925 he became consultant in neurology and mental diseases to the Royal Navy. He was lecturer in psychiatry at Middlesex Hospital, and in mental disorders at Maudsley Hospital. In 1931 he delivered the Maudsley Lecture to the Royal Medico-Psychological Association, and he was William Withering Lecturer of the University of Birmingham in the same year. He also examined in neurology and psychological medicine for the English Conjoint Board and later for the Universities of London and Leeds. The number of committees on which he served dealing with psychological medicine was very large. He was chairman of the Departmental Committee on Nursing in County and Borough Mental Hospitals, which reported in 1924, and a member of the "Shell Shock" Committee set up by the War Office in 1920–2. In 1934 he was appointed a member of a committee to advise and assist the Medical Research Council in the promotion of research into mental disorders. In many capacities he rendered great service to the Government, official bodies, academies, and medical societies. He was a man of alert and progressive mind, as energetic in decision as he was eager in speech, and he willingly gave of his large and varied experience in the discussions which accompanied and followed the Royal Commission on Lunacy and its sequel in the Mental Treatment Act of 1930.

Hubert Bond's name came prominently before the public in 1925 when, in an action brought against him by a patient, Mr. Harnett, he was mulcted in £5,000 damages. It was alleged that as a Lunacy Commissioner he had improperly detained a patient, and, with another medical man, had committed a tort by returning the patient to a licensed home for the reception of the insane and keeping him there and at other mental institutions for six years. The Court of Appeal, however, reversed the decision of the court below. The case was taken to the House of Lords, where five Law Lords, with the Lord Chancellor presiding, unanimously upheld the decision of the Court of Appeal. The case arose at a time when there was a good deal of public feeling over alleged improper detentions in mental hospitals, and Hubert Bond, as representing, so to speak, central officialdom and the "tyranny" of medicine—for the chairman of the Board of Control was a layman—came in for some very unjust abuse. Those who knew him never doubted his integrity and his extreme conscientiousness, especially in matters involving the liberty of these unfortunate subjects.

In the Royal Medico-Psychological Association Sir Hubert Bond was a prominent figure for many years. It rarely happened that its quarterly meetings passed by without some contribution from him. From 1906 to 1912 he was its honorary general secretary, and in 1921–2 its president. In 1928 the Association made him an honorary member. In 1922–3 he was president of the Section of Psychiatry of the Royal Society of Medicine, and in 1927 he was made an associate member of the Société Médico-Psychologique of Paris. He was vice-president of the Section of Mental Diseases at the Annual Meeting of the British Medical Association in 1927, and again at the Centenary Meeting of 1932. He was probably so much concerned in administration that he found no time to write a book, but he contributed papers to a number of journals on such subjects as mental hospital construction and management and the hospital treatment of the insane, and he paid eloquent tributes when former colleagues died. A noteworthy paper was given by him at the first Public Health Conference in London in 1928 on local organization for the prevention and treatment of mental diseases. He was made C.B.E. in 1920 and knighted in 1929.

F. F. MUECKE, C.B.E., F.R.C.S.

We regret to announce that Mr. Francis Frederick Muecke died on April 13 in the London Hospital, where he had been for many years surgeon to the ear, nose, and throat department. He was born in Queensland in 1879, son of the Hon. H. C. E. Muecke, of Adelaide, went to school at Prince Alfred College, and thereafter studied medicine at Adelaide University, where he won the Davies-Thomas Scholarship and graduated M.B., B.Ch. with first-class honours in 1902. An all-round athlete, he represented his university at cricket, lawn tennis, and lacrosse, and rowed in the boat. After serving as house-surgeon and house-physician at the Adelaide Hospital he came to this country and entered the London Hospital. He obtained the F.R.C.S. in 1909 and became assistant surgeon to the Central London Throat Hospital, aural surgeon to the Maida Vale Hospital for Nervous Diseases, and senior clinical assistant at the Golden Square Throat Hospital; he was elected to the staff of the London Hospital in 1909. On the outbreak of war in 1914 he joined the Army as lieutenant, R.A.M.C., was present at the Suvla landing, and took part in battles on the Somme and the Ancre, at Arras and Passchendaele. Before the end of the war he was transferred to the R.A.F. as lieut.-colonel, and he received the C.B.E. in 1919. Returning to his practice in ear, nose, and throat work Muecke published a number of papers in medical journals and was appointed consulting specialist to the L.C.C. He joined the B.M.A. in 1906, and held office as honorary secretary of the Section of Laryngology at the Glasgow Meeting in 1922, vice-president of the Section of Laryngology and Otology at the Winnipeg Meeting in 1930, and president of the Section of Oto-rhino-laryngology at the Melbourne Meeting in 1935. On his retirement from active work the London Hospital made him consulting surgeon to his department, and he went to live at Charlwood in Surrey.

Mr. H. S. SOUTTAR writes:

Francis Muecke will long be remembered both for his great personality and for his distinction as a surgeon. He came to England from Australia in 1903, and joining the London Hospital took the F.R.C.S. from there and was elected to the staff in 1909. He threw himself with great ardour into the work of the very busy E.N.T. department and rapidly achieved a reputation both for his work and for his teaching. In 1905 he had married Ada Crossley, the great Australian singer, and he acted as her manager in one of her Australian tours. In the last war he was one of the first to join the Army in 1914. In the surgery of the ear, nose, and throat he achieved distinction, and at the Melbourne Meeting of the B.M.A.

he was president of the section. He gained a large private practice, especially among singers, but he will be best remembered for his great social gifts, for his warm-hearted friendship, and for his generous personality. He was an ardent Freemason and rose to great distinction in the craft, devoting unstinted time and energy to its interests. He was a good fellow and he will be sadly missed.

Prof. Major Greenwood writes: The death, at the age of 87, of Ellen, widow of Sir Shirley Murphy, recalls happy memories of a past now becoming distant. Among other admirable qualities, Shirley Murphy's kindness to younger men was conspicuous, and Lady Murphy also had the gift of putting young people at their ease. Some of us still think with pleasure of drinking tea with the Murphys in Bentinck Terrace, of the kindly wisdom of our hosts, who gave good advice genially and could correct an ill-informed opinion without wounding youthful vanity. To Lady Murphy her husband's death in 1923 was a shattering blow borne with quiet heroism. She had shared all his interests and assiduously performed services few literary assistants can undertake. She was a good linguist and seemed to know every book and pamphlet in his library. The void could not be filled, but by giving unobtrusive help to others—first in the Library of the National Institute for Medical Research, later to the Red Cross—she was able to serve the cause in which her husband was a pioneer. Lady Murphy was a generous donor of books and statistical apparatus to the Library and Statistical Department of the London School of Hygiene and Tropical Medicine. When she left Bentinck Terrace she continued her patient work in the target area. A long life of quiet service to learning is over.

Medical Notes in Parliament

Amoebic Dysentery

On April 10 Dr. Morgan asked the Secretary of State for the Colonies whether his medical advisers had any statistics giving the incidence of cases of amoebic dysentery in the East African Colonies from below Egypt to the Cape; whether any modern research had been undertaken in the past decade on this problem, comparing native and European incidence; whether any report or results of any research investigations had been published or had reached his Department; and whether treatment not only by ipecacuanha products but by the more recently discovered sulphonamide drugs had been fully tried out and with what comparative results.

Col. Stanley said that the latest figures available for the East and Central African territories were:

Territory	Year	Number of Cases of Amoebic Dysentery
Kenya	No figures available	
Uganda	1943	754
Tanganyika	1943	1,010
Zanzibar	1943	15
Northern Rhodesia	1939	78
Nyasaland	1939	44

Exploration of methods of treatment of amoebic dysentery was proceeding continuously, and he had no reason to believe that there had been any alarming increase in the incidence of this disease in these territories in recent years, or in the mortality from it. Experiments with the sulphonamides had shown that they had no effect in amoebic dysentery. The main line of treatment was emetine bismuth iodine (an ipecacuanha derivative), combined with the use of oxyquinoline. Recent work had been done with diodoxyquin and had been described in the African journals, and had been and was going to be described in the *Tropical Diseases Bulletin*—the journal of the Bureau of Hygiene and Tropical Diseases. The full study of European and native incidence would require a large investigation staff which was not available at present.

Supply of Nurses

According to a reply made by Mr. Willink on April 12 the total number of additional nursing staff of all grades estimated to be required on Nov. 1, 1944, at civilian hospitals (other than maternity hospitals and mental hospitals) was 12,355. On the same date the number of student nurses in training in these hospitals was 38,343. He said the over-all shortage had not been reduced during the past year, the wastage having slightly exceeded the considerable intake. Every practicable step was being and would be taken by Mr. Bevin, in consultation with him, to induce suitable women to undertake nursing and to redistribute the available nurses to the best advantage. The highest priority was also given to the filling of vacancies for domestic staff in hospitals.

Smallpox in India

On April 17 Mr. Amery informed Mr. Viant that smallpox deaths in British India in 1938 and 1939 totalled 38,844 and 48,104 respectively. He had no complete figures for the subsequent years and was asking the Government of India whether they could supply them. He was also consulting them as to the extent of the statistical information available to their Public Health Commissioner about smallpox in the Indian States.

Antivaccination Literature

On April 17 Sir William Davison asked the Minister of Health whether he would introduce legislation to prevent the circulation of pamphlets implying that vaccination was likely to result in the death of newly born infants, especially in view of the pain caused to mothers of recently born children by pamphlets such as those in the form of a death certificate of a five-months-old baby, the misleading nature of their contents, and the shortage of paper. Miss Horsbrugh: No, Sir. Much as the Minister deplores the activities referred to, and the mischief and pain which they cause, he is not satisfied that they afford ground for interfering with the free expression of opinion in this matter. He thinks that parents are usually wise enough to be guided by the advice of their own doctors.

Wheat Germ for Commercial Products

On April 17 Mr. Mabane, replying to Sir E. Graham-Little, said that the medical products for which wheat-germ was now supplied were: Bemax, Froment, and C.V.B., and preparations made by Allen and Hanburys Ltd., Glaxo Laboratories Ltd., Bickiepegs Ltd., A. C. Whitehead, and J. and M. Glaskie. The amount of germ provided for these products was less than 1% of the total germ contained in the wheat which was milled in this country. The selection of these products was determined by his Department, which obtained the necessary medical advice by consultation with the Ministry of Health. Mr. Mabane also informed Sir Ernest that wheat germ supplied to firms preparing certain medical products was extracted from the wheat in the milling of flour for manufacturing purposes. This wheat might consist of home-grown or imported wheat. Manufacturing flour from which the germ had been extracted was, so far as possible, supplied for purposes where the processes involved would destroy the nutrients in germ.

Local Government Boundaries

The Local Government (Boundary Commission) Bill recently presented to Parliament provides for setting up machinery for a comprehensive review of local government areas in England and Wales, outside London. A Local Government Boundary Commission consisting of a chairman, deputy chairman, and three other members is proposed. This is to be an executive body, with powers embracing the existing powers of county councils and of the Minister of Health in relation to county reviews. The creation and extension of county boroughs and, in proper cases, the reduction of status of a small county borough, and the union of county boroughs and of some of the smaller counties will be within the scope of the Commission; but the exercise of these latter powers will be subject to Parliamentary review. The Commission will function according to general principles and procedure laid down in regulations to be made by the Minister of Health and approved by Parliament.

The decisions of the Commission are to be embodied in Orders, and when once an Order has become effective, no further action is to be taken concerning that area for ten years unless the Commission is satisfied that there are substantial changes in population or other exceptional circumstances.

German Prison Camps: M.P.s' Visit

In the House of Commons on April 19, in reply to a question whether the Allies would retain the captured prison camp of Buchenwald intact as a memorial of German methods, Mr. Churchill said that while no words could express the horror felt at the proofs of these frightful crimes he did not at present wish to commit himself to any special policy such as that suggested. He had that morning received a message from General Eisenhower saying that the new discoveries, particularly at Weimar, far surpassed anything previously exposed, and inviting Members of Parliament at once to his headquarters in order that they might have first-hand proof of these atrocities. The matter was urgent as, of course, it was not possible to arrest the processes of decay in many cases. Eight members of the House of Commons and two of the House of Lords would form a Parliamentary delegation and travel out at once to the Supreme Headquarters, where General Eisenhower would make all the necessary arrangements for their inspection of the scenes, whether in American or British sectors.

Artificial Insemination of Women

On April 19 Mr. DRIBERG asked the Minister of Health if he could make a statement on the experiments in artificial insemination of women, and if any births had resulted or were expected shortly to result therefrom. Mr. WILLINK: So far as my information goes, this operation is being performed with donated semen on a small scale in this country in cases where at the joint request of the husband and wife the responsible medical practitioner has satisfied himself that it is desirable. I do not think that the subject as a whole is one which can be satisfactorily discussed within the limits of a Parliamentary question and answer, but I think it right to say that I am advised that it would be a breach of the law to register as legitimate a birth which occurred as a result of this operation when the husband is not in fact the father of the child. Later Mr. Willink added that he was inquiring into the whole matter.

Examination of Contacts of Tuberculosis.—Mr. PARKER, on April 12, suggested that the Minister of Health should make it compulsory for all persons living in a household where a death from tuberculosis had taken place to be medically examined. Mr. WILLINK refused to do this. He said tuberculosis authorities were well aware of the importance of supervising the home contacts of tuberculous persons, although this work had been hampered by war conditions.

Notes in Brief

Major Lloyd George states that he is aware of the work for the prevention of silicosis being carried out in Canada and the United States of America. This is being considered by the Medical Research Council and his medical advisers.

Sir John Boyd Orr, the newly elected member for the Scottish Universities, took his seat in the House of Commons on April 17.

The Services

Temp. Surg. Lieut. A. J. Whitaker, R.N.V.R., has been mentioned in dispatches for good service while serving in H.M.S. *Frobisher* in the maintenance of the small craft during the invasion of Normandy.

Capts. J. J. Y. Dawson and J. M. Hamilton, R.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in Burma.

Capt. C. A. G. Cook, R.A.M.C., has been awarded the George Medal in recognition of conspicuous gallantry in carrying out hazardous work in a very brave manner.

The following appointments and awards have been announced in recognition of gallant and distinguished services in Italy:

O.B.E. (Military Division).—Cols. (Temp.) J. C. Barnetson, P. F. Palmer, and G. A. Walmsley; Lieut.-Cols. (Temp.) F. V. Allen, H. A. Brittain, A. C. Cox, D. M. Lyon, H. O. MacC. Merewether, L. H. Murray, R. V. Phillipson, J. C. Reed, W. H. Valentine, and G. E. W. Wolstenholme; and Lieut.-Col. (Acting) N. G. G. Talbot, R.A.M.C.

M.B.E. (Military Division).—Majors (Temp.) R. J. V. Battle, R. Cox, S. W. J. Harbutt, W. A. Heggie, M.C., R. A. King, C. S. Pope, H. B. Porteous, R. D. Rutherford, Barbara B. Stimson; and Capts. D. H. Jones, D. Macdonald, J. N. U. Russell, and M. G. Sutton, R.A.M.C.; Lieut. H. B. Sen, I.A.M.C.

M.C.—Capts. J. T. A. Essex, J. K. Mackay, and D. C. Watson, R.A.M.C.

The following appointments and award have been announced in recognition of gallant and distinguished services in North-West Europe:

O.B.E. (Military Division).—Col. W. E. Hume; Lieut.-Cols. C. U. Letourneau, G. L. M. Smith, and E. E. Tieman, R.C.A.M.C.

M.B.E. (Military Division).—Majors L. G. Alexander, M.C., G. C. McGarry, W. T. Mustard, and A. E. Thoms, R.C.A.M.C.

M.C.—Capt. J. H. Fraser, R.C.A.M.C.

Repatriated.—Capt. John Borrie, N.Z.M.C.; Capt. H. D. Fleming, R.A.M.C.; Capt. R. M. Solomon, R.A.M.C.

Released from captivity.—Capt. J. H. Mulligan, R.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Killed by enemy action in Burma.—Fl. Lieut. Sydney Wetherell, R.A.F.V.R.

Died.—Lieut.-Col. Hampton Atkinson Dougan, M.C., R.A.M.C.

Reported prisoner of war.—Capt. J. J. W. O'H. Tobin, R.A.M.C.

Medical News

A meeting of the Medical Society for the Study of Venereal Diseases will be held at 11, Chandos Street, W., to-day (Saturday, April 28) at 2.30 p.m., when Dr. A. H. Harkness will give an address on "The Cutaneous Manifestations of Gonorrhoea."

A joint discussion by the Biochemical and the Nutrition Societies will be held at the London School of Hygiene, Keppel Street, London, W.C., to-day (Saturday, April 28), the subject being "The Vitamin B Complex." The sessions will be from 11 a.m. to 1.15 p.m., and from 2.15 p.m. to 4.15 p.m. Speakers will include Drs. L. J. Harris, E. Kodicek, J. H. Quastel, F. A. Robinson, B. C. J. G. Knight, B. S. Platt, R. A. Webb, and L. Wills.

A meeting of the Society of Public Analysts and Other Analytical Chemists will be held at the Chemical Society's Rooms, Burlington House, Piccadilly, W., on Wednesday, May 2, at 5 p.m., when papers will be read and discussed.

The Children's Moral Welfare Committee (Rescue and Preventive) for the boroughs of Holborn, St. Pancras, and Hampstead, will hold its annual meeting in Holborn Town Hall on Wednesday, May 2. The general meeting at 6 p.m., under the chairmanship of the Mayor of Holborn, is open to all. The speakers are Dame Lilian Barker, former Governor of H.M. Borstal Institution for Girls, and Mr. S. H. Wood, C.B., former Assistant Secretary to the Ministry of Education. The chairman of the committee is Dr. Alan Moncrieff, and the honorary secretary Mrs. Christy Clay, 93A, King Henry's Road, N.W.3.

A meeting of the Medical Society of the L.C.C. Service will be held at the County Hall, S.E., on Thursday, May 3, at 4.30 p.m., when there will be a discussion on "Haematemesis," to be opened by Mr. J. R. M. Whigham, Mr. Norman C. Tanner, Dr. B. Gottlieb, and Dr. H. E. S. Pearson.

On Friday, May 4, at 8.30 p.m. at Whipps Cross Hospital, Dr. H. B. May, Acting Director, Clinical Laboratories, London Hospital, will give an address on the uses and limitations of penicillin. All medical practitioners in the district are invited.

The Association for Moral and Social Hygiene announces that the first Alison Neilans Memorial Lecture will be given by Dr. Louisa Martindale, F.R.C.O.G., on Thursday, May 10, at 6 p.m. in the Caxton Hall, Westminster, S.W. The title of the lecture is "Venereal Disease. Its Influence on the Health of the Nation: Its Prevention and Cure." Lord Balfour of Burleigh will take the chair.

An address on "*X*-ray Analysis: Past, Present, and Future" will be given by Sir Lawrence Bragg, D.Sc., F.R.S., before the Royal Institution (21, Albemarle Street, W.), on Friday, May 11, at 5 p.m.

The Birthday Trust Fund has prepared an illustrated lecture called "The Expectant Mother," for use in ante-natal clinics of hospitals, etc. The new synchrophone process has been used, and a preview of the lecture is being given at Queen Charlotte's Hospital this week.

At Liverpool Assizes on April 16 a cable worker named Rogers, of Bootle, was found guilty but insane, on a charge of murdering Dr. Alfred George Stewart, aged 65, of Great Crosby, by hitting him on the head with a pedestal telephone receiver in his surgery. Dr. Stewart died from his injuries on March 19. The medical officer at Walton Prison gave evidence to the effect that Rogers was suffering from schizophrenia. He was ordered to be detained during the King's pleasure.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week the total notifications for infectious diseases fell by the following amounts: dysentery 88, whooping-cough 80, acute pneumonia 53, diphtheria 42, scarlet fever 18; the incidence of measles rose by 416.

There were 54 fewer notifications of whooping-cough in Yorks West Riding, and 23 fewer in both Lancashire and Middlesex. A higher incidence of measles in the south more than balanced the fall in the north; the largest increases over last week's totals were Essex 278, Middlesex 211, Monmouthshire 122, Southampton 151, Sussex 120, Derbyshire 121, Gloucestershire 92; and the largest decreases were Yorks West Riding 404, Staffordshire 340, Warwickshire 182, Yorks East Riding 118.

The only fresh outbreak of dysentery of any size during the week was in Worcestershire 14 (Halesowen M.B. 11). The largest centres of infection were Lancashire 44, London 33, Surrey 23, Suffolk 14, Essex 12, Yorks West Riding 12, Gloucestershire 11, Staffordshire 11, Bedfordshire 10, Hertfordshire 10.

In *Scotland* measles notifications fell by 73, whooping-cough by 34, and diphtheria by 10, but those for acute primary pneumonia rose by 29, and for scarlet fever by 21. Dysentery remained at last week's level; the largest returns were Edinburgh 46, Glasgow 36, Aberdeen Burgh 11, Falkirk 11. Two cases of smallpox were notified during the week—1 in Glasgow, and the other in Motherwell and Wishaw.

In *Eire* the only variations of any size in the notifications were increases in measles 25, and whooping-cough 27, and a fall of 21 for scarlet fever.

Vital Statistics for the First Quarter of 1945

The notifications of infectious diseases during the first quarter of this year show some interesting contrasts with other quarterly returns. As some months will elapse before the official quarterly returns are published, it may be of interest to make a comparison with the returns from the weekly reports. The notifications of measles and dysentery reached new high levels, while diphtheria notifications were the lowest ever recorded; deaths from influenza were fewer than in recent years. The totals for England and Wales during the first quarter of recent years are:

	1940	1941	1942	1943	1944	1945
Scarlet fever	13,399	16,099	14,935	26,759	26,962	19,163
Whooping-cough ..	7,441	44,160	18,325	23,005	26,141	19,780
Diphtheria	9,199	14,533	11,658	10,799	9,005	6,061
Measles	51,377	204,158	26,535	225,056	20,278	247,455
Acute pneumonia ..	23,315	20,190	15,766	18,211	14,977	14,782
Cerebrospinal fever ..	5,093	4,332	2,412	1,287	978	968
Dysentery	531	1,757	1,674	1,319	2,834	4,681
Paratyphoid and typhoid	194	238	235	175	111	140
Influenza deaths in the great towns	4,568	2,217	863	1,149	1,131	692

The experience of the great towns suggests that the high birth rate of the past two years has been maintained, but the general death rate and the infant mortality rate have risen slightly. The case fatality of whooping-cough has increased, while the rate for diphtheria has dropped still further. The rates for scarlet fever and measles are above the 1944 level, but below that for 1943. A comparison of the March quarter is:

	1940	1941	1942	1943	1944	1945
Births	78,902	67,037	72,692	83,801	90,100	87,124

Quarterly Returns for Eire

During the December quarter of last year the birth rate was 20.2, being 0.1 above the fourth quarter of 1943. The infant mortality was 81, which was 3 less than the rate for the preceding December quarter but 6 above the average of the five preceding fourth quarters. Maternal mortality was 1.4 per 1,000 registered births, compared with 2.2 for the fourth quarter of 1943. The general death rate was 14.2 per 1,000, being 0.6 below the rate for the preceding December quarter but 0.9 above the average of the five preceding fourth quarters. Of the 401 deaths attributed to the principal epidemic diseases, 254 were due to diarrhoea and enteritis under 2 years of age, 81 to diphtheria, 40 to whooping-cough, and 13 to typhoid fever.

The provisional summary for the year shows a birth rate of 22.0 compared with a five-years average of 20.3. The death rate, 15.4 per 1,000, was the highest of recent years; during 1939–43 it fluctuated between 14.1 and 14.7. With the exception of 1943, the number of deaths from the principal epidemic diseases, 1,807, was the greatest of recent years. This group included: diarrhoea and enteritis 1,069, diphtheria 296, whooping-cough 240, measles 133, typhoid fever 59. Deaths from pulmonary tuberculosis and from other forms of tuberculosis numbered 2,884 and 874, being respectively 514 and 34 less than last year's total. A very high infant mortality was recorded in the cities; the largest were Limerick C.B. 136, Dublin C.B. 125, Cork C.B. 115. The blackest spots in Dublin C.B. were North City No. 3, and South City No. 3, with rates of 268 and 200 per 1,000 births.

Week Ending April 14

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,215, whooping-cough 1,234, diphtheria 438, measles 20,342, acute pneumonia 664, cerebrospinal fever 70, dysentery 463, paratyphoid 2, typhoid 8.

No. 14

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended April 7.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

---

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Sinus Formation

Q.—*What is the exact pathological mechanism involved in sinus formation in the presence of foreign bodies until they are extruded?*

A.—A foreign body which is sterile may become embedded deeply in the body tissues and remain there indefinitely without suppuration or sinus formation. But if a foreign body is present in an infected wound, suppuration must continue until it is removed; the greater part of the wound may heal, leaving the unhealed portion—the sinus—as an exit for pus. It must be added that an old-standing sinus, which is lined by granulation tissue and surrounded by fibrous tissue which thickens and hardens with the passage of time, may not heal even after removal of the foreign body; the track itself must be completely excised as well.

Acute Synovitis

Q.—*In a thin, elderly, female patient a skiagram shows commencing osteo-arthritis of the left shoulder, with a small loose body. There is the usual muscular wasting, but no other disease. (a) What is the explanation of the pain, and why is it always "worse at night"? (b) What is the best treatment for these pains? (diathermy, infra-red, and massage have been tried). (c) In view of the liability of separation of more osteophytes, is massage in such cases contra-indicated?*

A.—Muscular wasting is not the rule in osteo-arthritis, except the slight degree resulting from disuse. It suggests acute synovitis with some effusion into the joint or the subacromial bursa, which may be due to the loose body being nipped between the articular surfaces of the joint. The pain also indicates some inflammatory condition, as it is not usual in simple degenerative osteo-arthritis except on movement; the fact that it is worse at night may in this case be the result of posture. So far as the writer is aware no satisfactory explanation has been given of the pain in rheumatic conditions being worse at night; but the fact that there is nothing then to divert the attention probably has a bearing, and for its relief at such times aspirin or other analgesics are available.

As to treatment, removal of the loose body might reasonably be considered, because nipping is likely to recur and thus keep up the synovitis. Immobilization of the joint by strapping or bandaging it to the side is desirable; in an elderly patient the latter is to be preferred. In these cases moist heat is frequently more effective than dry heat for the relief of pain, and the effect can be kept up afterwards by the use of salicylate liniments. Although ankylosis does not occur in simple osteo-arthritis of the joints of the limbs, adhesions are likely to form between the folds of the capsule if there is any inflammation from synovitis, and therefore the joint should be moved to its full extent once a day passively. It is very unlikely that any osteophytes would be detached by massage, which, however, should be only light unless there is some indication of adhesions, and it should then be local and purposive and not a general "rubbing." Ionization with histamine followed by light effleurage is often useful in relief of pain; and, when the symptoms are less acute, surging faradism to restore the wasted muscles is indicated. When the pain has subsided and immobilization can be given up, it is desirable that for some time the arm should be worn in a sling to relieve the strain on the muscles and ligaments of the shoulder from the weight of the dependent arm.

Opium causing Spasm

Q.—*Why does the giving of opium and its alkaloids cause spasm of the sphincter of Oddi with resulting pain and vomiting in some patients who have previously had cholecystectomy?*

A.—Several of the alkaloids of opium, but not all, have long been known to cause spasm of various sphincters, including the sphincter of Oddi. Actually, the effect on the flow of the bile is due to a spasm of the lower end of the common bile-duct, as was shown by the experiments of Butsch, McGowan, and Walters (*Surg. Gynec. Obstet.*, 1936, **63**, 451), who took *x*-ray pictures and measured the intrabiliary pressure. They found that gr. 1/6 of morphine sulphate raised the pressure from 2 cm. to 20 or even 30 cm. water. Pain was found to follow morphine administration in patients with a "post-cholecystectomy syndrome." In these the pressure rose to 40 or 45 cm. water and remained high sometimes for 2 hours. Both the spasm and the pain were relieved by inhalation of amyl nitrite. Schondube and Lurman (*Münch. med. Wschr.*, 1927, **74**, 1906) found that giving atropine after morphine failed to relieve the spasm. Papaverine is an alkaloid of opium which does not produce spasm, but actually relaxation. To relieve pain in patients who have had a cholecystectomy, pethidine might also be tried. It does not produce spasm, and does not produce vomiting in those in whom morphine causes vomiting.

Quarantine for Chicken-pox

Q.—*As a school medical officer I have been keeping children suffering from chicken-pox in the sanatorium till the last scab has separated. This often prolongs quarantine well into the school holidays, much to the annoyance of staff and patients. An authority recently told me that the safe period of quarantine from chicken-pox was nine days from the appearance of the last spots. He states that as the virus is spread from the nasopharynx the infectivity does not depend on the presence of scabs. What is the correct procedure?*

A.—Although the viruses of smallpox and chicken-pox are probably disseminated mainly by mouth and nasal secretions early in the disease, there is no doubt that elementary bodies are constantly demonstrable in the skin eruption in both diseases. As there is no laboratory method of determining readily how long the virus in the skin lesions actually remains infective, it is still common practice to maintain strict isolation until the last crust has separated. Nobody questions this in smallpox, but many clinicians of wide experience have maintained that chicken-pox is not infective in the late stages even if all crusts have not separated. The writer's practice is to release from isolation after a period of 7 to 10 days provided that a careful search, particularly of the scalp, reveals that *all lesions* have progressed beyond the stage of pustulation to firm crusting. If this standard is adopted strictly, clinical experience indicates that secondary cases of chicken-pox do not result.

Vaso-vagal Attacks

Q.—*A clergyman aged 33 has for two and a half years and about twice weekly suffered from attacks of giddiness, nausea, tachycardia, choking sensations, or tightness round the upper chest. Attacks have occurred in bed. On one occasion—when he was sawing wood—consciousness was completely lost. The attacks last about half an hour and gradually subside. He is active, a non-smoker, and a total abstainer. He invariably has an attack on Sundays when his duties are heavy. His heart is enlarged to the left and his B.P. is 145/110. Urine, blood urea; B.M.R., x-ray of skull—all normal. Petit mal has been excluded. Is this a case of hypertensive pseudo-uraemia? Do the attacks have any relation to carotid sinus syncope? What other possible causes may there be?*

A.—It is difficult to believe that a youngish man could have had hypertensive crises for two and a half years with no more to show for them than this. What is the evidence that the heart is enlarged to the left, and how far is it enlarged? If there is cardiac enlargement, a silent aortic stenosis should be suspected, as this can be the most puzzling of all heart lesions. *X*-ray pictures of the heart and electrocardiographic tracings would help in proving or disproving this suggestion. Retrosternal goitre is another possibility. The attacks do not sound like carotid sinus syncope, which could in any event be demonstrated by manual pressure on the sinus.

Having mentioned these organic possibilities, one must state frankly that it is more likely that the attacks are psychogenic, the so-called vaso-vagal attacks. Blood pressures of this order are quite common in "effort syndrome." The questioner does not tell us what manner of man his patient is, and under what circumstances the attacks first began. Vaso-vagal attacks often seem to be the acting out of death fears, and these again are sometimes the obverse of death wishes. Like girlish faints, they are prone to occur under the strain of religious worship. The possibility that there is an underlying cardiac dysrhythmia akin to epilepsy should nevertheless not be forgotten. This might be revealed by an electro-encephalogram.

Immunization against "Influenza"

Q.—*I have annual "influenzal" illnesses. Can I protect myself against these and so avoid them?*

A.—Influenza is a loosely used term to indicate upper respiratory infections of varied aetiology. If the sufferer from "influenzal" bouts wants to try a protective vaccine, he should consult a bacteriologist during or immediately after an attack, so that the bacterial flora of his upper air passages can be sampled for pathogens. He may, for example, be addicted to recurrent sinusitis which is lit up by some primary virus infection such as the common cold or influenza. If a specific pathogen like the pneumococcus, haemolytic streptococcus, *Staph. aureus*, or Friedländer's bacillus is found, an autogenous vaccine is often beneficial. Some patients seem to benefit from a mixed stock vaccine taken in the autumn. It is unlikely that these annual attacks are due to specific infection with the influenza virus, but an influenza virus A vaccine is now available, and could be used if there were evidence of epidemic influenza in the country. Any sufferer from recurrent "influenza" should have an *x*-ray examination of his chest.

Neuralgia in Mandible

Q.—*A man of 56, edentulous for 10 years, has had slight neuralgia in the left mandible for 6 weeks. The denture has been altered where it is pressing. X-ray examination suggests a residual infection, and dental advice is incision and cautery if discomfort continues. What is the prognosis if untreated; and is there any alternative treatment, such as penicillin?*

A.—The history of 6 weeks' slight pain after being edentulous for 10 years does not suggest a simple residual infection. Presuming that there is no radiographical evidence of any retained portion of root, dead bone, or foreign body such as a small piece of amalgam filling, it is more than likely that the lower denture is at fault and pressing somewhere too hard in spite of the previous adjustment, especially if there has been considerable absorption of alveolar bone. Vague pains most often occur in patients who are below par, overworked, or in a state of anxiety, and attention must be paid to their physical and mental health before embarking on any surgical intervention. The possibility of early malignant disease of the tongue or pharynx should be kept in mind. An incision stripping the mucoperiosteum from the bone, and gentle curettage, is often tried, but the use of the cautery is not without danger. It is difficult to see how chemotherapy could help in a case of this nature. Most of these cases of slight neuralgia recover in spite of rather than because of treatment.

Sulphonamides and Otitis Media

Q.—*What is the present position with regard to the treatment of (a) acute, and (b) chronic otitis media with sulphonamide drugs—as, for example, sulphathiazole applied locally? Can it be used in the treatment of a chronic discharging ear?*

A.—(*a*) Local treatment by sulphonamides is irrational, because it is not feasible to get the drug in contact with the infection, and because it is inactivated by pus. Indiscriminate administration by mouth is condemned, because it tends to mask symptoms, and may lead to permanent impairment of hearing. Sulphonamides should never be given in inadequate dosage or in the presence of undrained pus. Therefore it is wise to employ conservative treatment, including myringotomy, if indicated, withholding sulphonamides until it appears that the infection is not likely to resolve otherwise. In that event the patient should be kept in bed, and given the full doses under the usual precautions, and watched until clinically, and if necessary radiologically, complete resolution has occurred.

(*b*) Various sulphonamides have been applied locally in chronic otitis media, either in solution or in powder form. Obviously they are contraindicated in the presence of cholesteatoma, and of widespread bony necrosis with granulations, and they cannot be expected to succeed with insensitive organisms such as *B. proteus* and the coliform group. But there is no reason why they should not be employed empirically in other cases, provided the powder is not allowed to accumulate as a cement-like deposit, and a fair number of dry ears may be thus obtained.

Doctors Attending their Own Families

Q.—*What is the attitude of the medical and legal professions on the practice of attending one's own wife and family, particularly with reference to performing surgical operations, managing confinements, and administering anaesthetics? In the "outposts of Empire" there may be no option, but in this country some people look on the practice with some surprise and disfavour.*

A.—A doctor who treats a member of his own family is required by law to use the same degree of skill and care and to behave in all respects as though he were treating a stranger for a fee. No particular legal question arises from the doubling of the relationship. This is the legal view The writer knows of a case in which a doctor operated on his son for appendicitis, and the son died on the table. What would have been a regrettable professional experience became a personal tragedy. If a medical man has exceptional skill in the surgical treatment of a rare condition, it is understandable that he would be reluctant to have a member of his family treated by anyone else. But for the treatment of conditions within the competence of the average general surgeon, most medical men, we believe, would prefer to place the responsibility for treatment in the hands of a trusted colleague.

Sensitivity to Liver Extract

Q.—*A patient of 65 years with pernicious anaemia is on liver extract, and recently had a typical attack of angioneurotic oedema affecting tongue and lips, treated with ephedrine. There have been no further such attacks, but about ten minutes after the last two injections of liver extract the patient fainted; the body was in a tremor, and the face purple-black, with frothing at the mouth. The pulse was rapid and very weak. The faint lasted five minutes, but tremor of the limbs continued for some hours. There is no previous history of fits. Is this a case of immediate reaction of anaphylaxis? Can it be avoided?*

A.—This is clearly an example of the development of sensitivity to liver extract and the reaction is of an anaphylactic or allergic nature. The phenomenon is unfortunately not uncommon; several answers to questions on this subject have been given in this column (1943, **1**, 370 and 528; 1943, **2**, 29) and an article by McSorley and Davidson appeared in the *Journal* of May 27, 1944. Sensitivity to liver is more likely to develop if the interval between injections is extended beyond four weeks, and long intervals should therefore be avoided even though the patient seems to be enjoying a remission. It occurs with all brands of liver extract and is unrelated to the species of animal from which the liver is derived. It is dangerous and may be fatal, and it should therefore be treated by desensitization or by changing over to oral treatment with liver or desiccated stomach. In severe sensitization, such as the present patient shows, a skin test should be carried out with 0.05 c.cm. of liver extract. If this causes no generalized reaction, treatment is begun with 0.05 c.cm. intradermally. With this and all subsequent injections 0.2 c.cm. of adrenaline hydrochloride, 1 in 1,000, is given. The dose of liver extract is doubled every half hour, and the route of the injection is changed from the intradermal to the subcutaneous when 0.4 c.cm. is reached and to the intramuscular route at 1.0 c.cm. When a dose of 2.0 c.cm. has been reached, treatment is continued without adrenaline and one injection is given daily for a few days. The interval is then gradually increased till the patient is back to an interval of three to four weeks. Further details should be sought in the article mentioned.

Tinnitus Aurium

Q.—*Can you suggest treatment for cure or alleviation of persistent "tinnitus aurium"? The patient, a woman aged 68, for many years has been subject to an almost continuous high-pitched noise, sometimes in one ear, usually in both. Occasionally, for no ascertainable reason, the noise ceases, but recurs after the patient falls asleep. Hearing is normal, and examinations have discovered no physical cause for this distressing symptom.*

A.—Vascular changes in the cochlear and auditory nerve are responsible for tinnitus of the type described. Unfortunately, in a large proportion of cases the changes are permanent. This does not mean that such patients do not require help. They are often tortured by fears of cerebral tumours, of insanity, or of impending cerebral haemorrhage. A complete examination has not only the advantage that it may reveal a cause for the tinnitus, but it also forms the only sound basis for dispelling fears of a serious disease. Rarely, the routine examination of the function of the Eustachian tubes reveals unsuspected middle-ear and tubal catarrh as the cause of the altered blood supply of the labyrinth. Recently a number of favourable reports have been published on the use of vasomotor drugs in the treatment of tinnitus. For full details, the paper "Tinnitus Aurium," by Miles Atkinson, in the *Annals of Otology, Rhinology and Laryngology* (December, 1944, 53) should be consulted.

Blood-sugar Colorimeter

Q.—*While serving with the B.L.A. I came across a "blood-sugar colorimeter" which seems to be a simplification of the elaborate methods of MacLean or Folin and Wu. It was made by Zeiss, and on the lid of the case is described, "Blutzucker-Kolorimeter nach Crecelius-Seifert." It consists of a comparison colorimeter (transmitted light) with a focusing eyepiece; a square tube to contain the fluid for colour-matching and which fits into the colorimeter; a measuring pipette graduated at 0.1 c.cm. and 0.2 c.cm.; a filter funnel, stirring rod, and a container (bakelite), with filter papers and stamped "Made in Germany." I am interested to know more about this method of blood-sugar estimation.*

A.—This method and apparatus were introduced in 1928 by Crecelius and Seifert. It relies on the well-known reduction of picric acid to picramic acid, and the dark-brown colour is compared in the special colorimeter, which is graduated in mg. per 100 c.cm. This instrument and method have been criticized by Thiel on the ground that the wedge used is not fast to light and so gives high results. In general, only an approximate answer can be obtained, and it is not sufficiently accurate to supersede the usual analytical methods. The reagents are 1.2% picric acid and 10% sodium hydroxide. To 1.8 c.cm. of the picric acid solution add 0.2 c.cm. of blood; mix well, and filter through a very small filter paper. Take 1.5 c.cm. of filtrate, add 10 c.cm. of sodium hydroxide solution, and boil over a flame for exactly one minute. Cool, place in a colorimeter, and read off the result in mg. per 100 c.cm.. If the colorimeter is of any age it is advisable to check the calibration by means of a standard glucose solution.

Malaria and Syphilis

Q.—*If a person with syphilis contracts malaria does the latter infection have any "damping" effect on the former? May malaria mask syphilis altogether if the two occur together? There seem to be numerous cases of these "twin" infections (not necessarily simultaneous) in the Navy, yet I have seen no mention of this in the literature.*

A.—There is no evidence that malarial infection has any therapeutic effect on a *Treponema pallidum* infection. If the two occur together there might well be confusion in the diagnosis of either clinically. Blood examination should reveal the presence of the malarial infection, and the spirochaetal infection would be unaffected by treatment of this.

Contact Glasses for Corneal Scar

Q.—*A patient has a nebulous corneal scar which is now two years old and therefore probably cleared to its maximum. It is 4-5 mm. in diameter, and slightly eccentric toward the infero-lateral quadrant. Slit-lamp examination shows the full thickness of the cornea to be involved. For precision work the proposal is to use a contact lens, with a part or the whole of its extent painted over to mask the scar and at the same time to serve as a cosmetic improvement. Should the mask be complete or can peripheral vision be retained? How would such a lesion affect the prognosis of moderate myopia in the other eye?*

A.—Contact glasses with part painted over to mask a corneal scar have been tried. Whereas the cosmetic result has been satisfactory, the optical result has been disappointing. If the affected eye interferes with the work of the sound eye, it could be occluded by a painted contact glass, though there are other more simple and less expensive methods. Provided any correction necessary is worn before the sound eye, the prognosis of the myopia will not be affected.

Gynaecomastia after Testosterone

Q.—*A hypogonadal male aged 40 has been treated with testosterone propionate 25 mg. three times weekly, without noticeable improvement. He has, however, developed great enlargement of both breasts with darkening of the areola and enlargement of the nipples, accompanied by a constant burning sensation in them. Treatment has now been stopped for nearly three months, and while the burning sensation in the nipples has passed off the breasts are still enlarged and show no signs of regression. What treatment is indicated?*

A.—The symptoms described are to the best of my knowledge and experience unique, and are precisely those which develop if an oestrogen is administered. Though such complaints do not as a rule arise during androgenic treatment, there is experimental evidence that androgens have some effect on the male mammary glands. Folley, Guthkelch, and Zuckerman (*Proc. roy. Soc.*, B, 1939, **126,** 469) found that testosterone propionate stimulated stunted duct development and alveolar formation in male rhesus monkeys. Castration can prevent the normal increase which occurs in the mammary glands of male rats at puberty (McEwen, Selye, and Collip, *Proc. Soc. exp. Biol.*, N.Y., **35,** 56). In human males gynaecomastia associated with tumours of the testicles has usually been explained by assuming an increase in the oestrogenic secretion of the testicles. Gynaecomastia is commonly associated with testicular atrophy and consequent reduction in androgenic activity. The question of gynaecomastia was discussed in these columns on Nov. 6, 1943 (p. 597). It seems very improbable that the enlargement is permanent, and at present it would seem best to do nothing. Oestrogens would probably make the condition worse. Desoxycorticosterone can itself produce gynaecomastia (*B.M.J.*, 1943, **1,** 12) and is therefore contraindicated. If after a year the enlargement still persists, surgery should be considered.

INCOME TAX

Cost of Medical Books: Assistant

B. M. is employed as an assistant and has been refused a deduction for the cost of keeping up his personal set of medical books.

*** The rules applicable to the deduction of expenses in the case of salary of earners assessable under Schedule E are more stringent than those applicable to persons carrying on a profession or trade who are assessed under Schedule D. Schedule E requires that the expenses shall be incurred "necessarily" in the performance of the duties of the appointment. If B. M. can prove that his principals require him to maintain a set of medical books, then the expense is "necessary", and he is entitled to deduct it for income-tax purposes—in the absence of such a requirement his claim is not valid. (In the case to which B. M. referred the Schedule D rules were applicable.)

LETTERS, NOTES, ETC.

Memorial to Fl. Lieut. A. J. Sinclair, R.A.F.

The following letter, with six signatures, has been received for publication from the Dental Department of University College Hospital: We are anxious to perpetuate the memory of the late Mr. A. J. Sinclair, who was attached to the National Dental Hospital both as medical superintendent and sub-dean for many years. We are therefore, at the suggestion of a number of his late colleagues, proposing to establish a trust fund, the interest of which will be devoted to granting an annual prize, to be called the "Alfred Sinclair Prize." We are sure that many old students who have gained so much over many years by the help given by this inspiring teacher would wish to support this memorial, and are asking them to forward their donations, made payable to the "Alfred Sinclair Fund" and addressed to Mr. Alan Shefford, University College Hospital Dental School, University Street, W.C.1.

Artificial Respiration

Capt. **Alwyn E. Biscoe** (chief secretary, Royal Life Saving Society) writes: The letter from Dr. Frank C. Eve (April 7, p. 495) has been read with interest by my committee, and they entirely agree with his last paragraph that the time is ripe when a small expert subcommittee should be set up to investigate all methods of artificial respiration. But we should be interested to know upon what authority Dr. Eve states, that since the rocking method was introduced in the Navy the number of successful cases has increased, because we are given to understand on good authority that rocking methods are not being used in the Navy.

The Swallow

Dr. S. W. **Swindells** (Grimsby) writes: Your footnote (March 31, p. 470) interested me because when I used to climb the Pyrenees I got quite expert with the gourd and could hit the gullet without spilling a drop. You might perhaps have mentioned a reason for this extraordinary method of drinking. I think it was Belloc who said it was to avoid tasting the wine. Anyhow, it's a good reason; it's rather crude.

*** Especially on the Spanish side of the range.—Ed., *B.M.J.*

Scorpion Sting

Dr. **Frank Marsh** writes from Matlock: In the *Journal* of April 7 (p. 504) there is a note from Dr. E. G. Cohen on a case of scorpion bite. Scorpions *sting*, of course, with a hollow spine on the last abdominal segment. I have seen many hundreds of cases of scorpion sting. The severity of the sting varies with the age of the patient, the site of the sting, and the age and species of the scorpion. Bayer's (before the war) made a very good antiscorpion serum which was put up in glass pressure ampoules ready fitted with a hypodermic needle. This serum injected locally round the lesion was very beneficial. In the absence of serum 1 in 1,000 solution of potassium permanganate injected round the sting was effective. We did not use local analgesics or adrenaline. Children aged 2 to 5 years sometimes die after a scorpion sting—untreated. Bayer's serum saved many of their lives; none died after timely serum treatment. In adults the stings are often multiple; the first shows a circular area of necrosis, the second violent inflammation with a small necrotic spot at the centre, the third a mild inflammatory reaction, and the fourth just a puncture mark with a slight circumscribed reaction. One night I was wakened by—as I thought—a needle left by someone in the mattress. I turned on the light and investigated; a young yellowish-white scorpion 50 mm. from head to telson was lurking at the foot of the bed between the sheets. I had been stung three times: No. 1 the size of a bisected hen's egg; No. 2 the size of a pigeon's egg; and No. 3, just palpable. I adopted—from scientific interest—a "no-treatment" line; the pain vanished in 3/4 hour and I went to sleep. Next morning the affected buttock was a little stiff; 36 hours after the stings I woke very giddy, nauseated, with occasional vomiting, hot and cold by turns, and sweating. Symptoms passed off in two days leaving me rather weak. No other effects were observed except muscular cramps in the affected leg.

Sodium Sulphate Applications

Dr. F. **Gordon Cawston** (Durban) writes: Ready response to the application of strong sodium sulphate solution for aural discharge and even of magnesium sulphate solution for conjunctivitis confirms some reports in the *Extra Pharmacopoeia* and more extensive experience of these remedies for surface wounds and local swellings. I agree with those practitioners who do not favour the addition of glycerin, and consider that sodium sulphate solution loses much of its value if covered with jaconet.

Medical Aphorisms

F. C. writes with reference to Dr. Crawhall's inquiry (March 31, p. 470): Geoffrey Keynes, F.R.C.S., gives some aphorisms which appear in *St. Bartholomew's Hospital Journal* (July and Sept., 1933).

SOME APPLICATIONS OF THE SURGICAL LESSONS OF WAR TO CIVIL PRACTICE

BY

W. H. OGILVIE, M.Ch., F.R.C.S.

Major-General

Now that the European phase of the second world war appears to be entering its final stages, it may be well to consider briefly what war has taught surgery and what it has taught surgeons, and how the lessons learned in the field can be applied to the teaching and practice of surgery in civil life.

The surgery of wounds in this war has passed through three phases. In the first, treatment by the closed plaster method was the rule; in the second, which was a period of long communications and poor supplies, wounds were excised and drained, the limb was immobilized in a padded plaster case or some form of plaster box splint, and closure by secondary suture or skin grafting was attempted about the third week, or as soon as the surface was covered with healthy granulations; in the third phase, which has been helped by the advent of penicillin, the wounds are excised by the forward groups and closed by delayed primary suture at the base between the fourth and the sixth day.

These successive steps should be regarded as a gradual evolution to meet changing circumstances rather than as an advance in method due to surgical enterprise. Each step was the right one at the time. The closed plaster method is safe and gives excellent results under desperate conditions, when the wounded arrive in numbers too great to allow frequent supervision after operation. Free drainage, immobilization without constriction, chemotherapy, and the provision of skin cover at a later date are the only possible line of treatment in a swiftly moving campaign where all supplies are poor and many days of rough travel separate the forward operating units from the base hospitals. Such conditions are liable to recur, and where they do three-hourly penicillin, wound dressing under theatre conditions, and all the ritual of war surgery in the British armies of 1945 would be out of the question. When, however, conditions become good in a surgical sense—that is, when advance is steady and retreat unthinkable, when air cover ensures good hospital facilities and uninterrupted supplies, when advanced surgical centres are well placed and well administered and base hospitals are within easy reach by a good evacuation route—early closure, by delayed primary suture or by skin graft, becomes the rule. Even better conditions prevail in civil traumatic surgery, for the injured usually receive their first-aid and definitive treatment at the same hospital, and we can expect that the same methods will prove their value.

Two-stage Closure

The policy of delayed primary suture is a return to that which prevailed in the closing years of the war of 1914–18, but there is one important difference. In the last war delayed primary suture led, in many centres, to the practice of primary suture. In this war primary suture has been condemned for all wounds except those of the head, face, and trunk, partly because it has been tried repeatedly and found more than wanting, still more because it transgresses those basic principles which each war teaches us afresh. Recent wounds freshly excised look so like clean operation wounds that inexperienced surgeons, and also experienced surgeons new to a theatre of war, are tempted to suture them; unfortunately, they sometimes succeed, and persist in spite of warning, till the loss of a limb or a life teaches them their lesson. Except in the case of purely surface injuries, war wounds can never be rendered entirely healthy and entirely sterile by surgical toilet. The limits of tissue damage cannot be decided with any accuracy, and bacteria, blasted in by the cushion of air that precedes the projectile or displaced along tissue planes by movements of the limb, may lie well outside the visible confines of the wound track. Where the bacteria are few and the remaining damaged tissues small in amount, the defences of the body will soon turn out the invaders unless they are hindered by tension. In a sutured wound the hyperaemia which should give protection is limited by the unyielding surroundings and finally replaced by ischaemia, and the outpouring of defensive fluids is brought to a standstill when the interstices of the wound are filled; the bacteria, on the other hand, find in the trapped discharges an ideal pabulum and in the anoxic tissues an easy prey.

The wounds of road and industrial accidents are, like those of war, lacerated and contaminated, though they never show the extreme devitalization that is a fundamental factor in the pathology of wounds caused by modern weapons, nor are they often contaminated to the same extent. Nevertheless the same problems are present in each, and methods which have been found to confer safety and give good results in war wounds should be safer and better in the traumatic surgery of peacetime. The wisdom of unrestricted drainage during the first few days after an open laceration, when an unprepared body is summoning its defences against an unexpected invasion by pathogenic bacteria, the value of closure by suture or skin graft as soon as the defences are established and before the changes of repair have come to leave their train of deformity, pain, scar tissue, and limited movement—these are principles that we cannot well afford to ignore.

The methods in use to-day are simple, as all methods in the field must be, and the tests applied are clinical ones. At the primary operation the wound is carefully excised. Foreign bodies and dirt are removed and all damaged tissues are cut away. The skin is freely incised to allow access to every pocket, but only the barest edges are trimmed off. A simple dressing, usually vaselined gauze, is applied to the surfaces of the open wound, and the limb is immobilized in plaster.

As soon as the patient reaches hospital the possibilities of suture are assessed by the study of his general condition and of the notes of the first operation. He is rested for one day, during which any deficiency in his blood count is made up by transfusion. The wound is not inspected. The dressing is removed in the operating theatre under full aseptic ritual as the first step in the operation of closure, which is usually on the fourth to sixth day. Experience has shown that if the wound appears clinically healthy at this stage it can be sutured safely, even though it may prove on culture to harbour pathogenic bacteria. The wound surfaces are disturbed as little as possible, though some tags or pieces of exposed tendon left at the primary excision may be trimmed away before closure. The skin is brought into apposition by interrupted sutures of some unabsorbable material, which may also take up deeper layers, but no buried sutures are used. The limb is again immobilized in a plaster case, and the stitches are removed on the tenth to twelfth day.

4400

Skin Cover

It has been found that at this interval after the primary operation a certain amount of tension may be used to approximate the skin without danger. A covering of normal skin with subcutaneous fat gives a result so much better than the best graft that every effort is made to approximate the edges, and this is generally possible over the greater part of the wound. Where the skin edges cannot be made to meet, many surgeons prefer to mobilize them as swinging flaps to cover the wound of the deeper parts, and to cover the gap thus produced, whose base is undamaged muscle, with a graft. Normal skin over scarred muscles or an epithelial graft over normal muscle is functionally more satisfactory than a skin graft over an underlying scar.

The need to provide skin cover at the earliest possible date is now an article of surgical faith that will remain. Not till a wound is epithelized does the formation of granulation tissue stop and the scar left by previous granulations become absorbed or moulded along lines of stress in response to the call of function; not till then does the fight against infection cease to be a constant struggle to keep away or kill pathogenic bacteria. The technique of skin grafting has been perfected to a remarkable extent and, for the simpler procedures, brought within the scope of the non-expert. For covering unhealthy granulations to provide temporary epithelial cover, split-skin grafts cut into small pieces—so-called "postage stamp" grafts—have proved more satisfactory to the recipient and donor areas than pinch grafts. For large areas the Padgett dermatome has made it possible to cut split-skin grafts of any chosen thickness up to an area of 40 sq. in., for smaller areas to cut them to any desired shape, and to take skin from places, such as the abdominal wall, that could not formerly be used. The method of glueing grafts to their bed by a living adhesive made from mixed plasma and leucocyte extract, as described by Sano of Philadelphia, has proved an outstanding advance, permitting the provision of skin cover to surfaces that cannot be immobilized and to deep and irregular holes.

I would suggest that the principle of two-stage closure may prove applicable to the treatment of infections other than those caused by wounds or accidents. For more than 20 years drainage in abdominal emergencies has been unfashionable. It has had a poor press. Phrases such as "The peritoneum can look after itself" and "A tube in the belly drains only its own track" are freely used by young surgeons who never drain if they can help it, and the dangers of adhesions, of faecal fistulae, of erosion of vessels are quoted in further support. I would challenge most of these statements. A healthy peritoneum can deal with a considerable amount of infection recently introduced, but the peritoneum in the neighbourhood of a chronic abscess has lost much of its phagocytic power. A tube introduced into the normal peritoneum of an experimental animal may seal itself off, but one put into the infected belly of a man goes on draining while there is anything to come out and allows egress to infected fluid in the whole region from which it emerges. Faecal fistulae or haemorrhages may have been caused in the past by rigid tubes of glass or hard rubber left for long periods, but they do not follow the use of soft tubing or corrugated rubber. As to adhesions: which will cause the more—a tube-track or a collection of fibrin or pus slowly absorbed? In three years of service in Africa I observed many hundreds of patients with abdominal wounds, operated on by surgeons of varying outlook under many different conditions. I found that those who drained most got the best results. Not to drain, when in doubt, is needless bravado at the patient's expense.

But if the peritoneum can look after itself in the presence of a recent infection the tissues of the abdominal wall are less able to do so. It is a common experience after an operation for appendicitis or duodenal perforation to find that the peritoneal cavity recovers but the abdominal incision becomes infected and breaks down. The lesson of the surgery of soft-tissue wounds in war may well be applied to those cases in which the layers of the abdominal wall have been bathed in infected fluid during an emergency operation. After the intra-abdominal mischief has been dealt with the peritoneum alone is sutured, and the remaining layers dressed with gauze soaked in flavine or one of the newer acridine antiseptics, but left entirely open, or at most protected from evisceration by a few stout sutures through all layers. In four days' time, preferably after the bowels have been opened, layer closure is done under local or pentothal anaesthesia.

General Health of the Injured

But the surgical care of a wounded man to-day implies, besides the treatment of his wound, the restoration or maintenance of the general health, on which the health of the wound depends, and an attack on the bacteria that invade it. We seek to help his general powers of resistance by restoring lost blood early and in full amount and making good any later deficiency as it occurs, by keeping fluid reserves fully charged at a time when synthesis, elimination, and temperature regulation are calling for water, and by maintaining that positive nitrogen balance which is essential to the processes of immunity and repair. We can, for the first time in history, attack bacteria in the wound itself without harming healthy tissues. These things are now so much a matter of everyday routine that it is hard to realize that at the outbreak of war continuous intravenous therapy was by no means universally practised, transfusion was seldom given in greater quantities than two pints a day, stored blood was a curiosity and stored plasma unknown, and the use of sulphonamides was being tentatively explored. Penicillin and accurate methods for bedside estimation of haemoglobin and plasma protein have been available only within the last two years. These methods will remain an essential part of the care not alone of our injured but of our sick in civil life.

Blood and Protein

That tissues require a supply of blood fully charged with cells and proteins to carry out their processes of repair, that the most effective antiseptic against anaerobic invaders is oxygen and the most effective applicator of oxygen is the erythrocyte—these are truisms when set down on paper; yet their truth has been realized only slowly, as the result of the clinical observations that men with a haemoglobin of less than 70% show little evidence of repair in their wounds but start to do so after a transfusion of two pints, that men whose blood loss has been fully restored within a few hours of wounding seldom get gas gangrene. Anaemia must be constantly watched for and suspected in any patient whose progress is unsatisfactory; for it tends to appear insidiously, quite apart from any recognizable blood loss, in the wounded, the burnt, the sick, the victims of any infection, not alone those by organisms known to be haemolytic, and to reappear after correction.

The greatest surgical advance of this war, more important even than penicillin, is the development of the transfusion service. This advance we owe entirely to two British officers —Brig. Sir Lionel Whitby, who designed the instrument, and Lieut.-Col. G. A. Buttle, who taught us how to use it. It was in the Middle East, during the thrust of the Eighth Army across Africa from Alamein to Tunis, that the provision of whole blood to the forward operating units was first organized on a satisfactory scale, and that the life-saving importance of early, rapid, and adequate restoration of blood volume in haemorrhage and shock was first learnt. To-day we know no limits, in amount or rate of administration, other than the needs of the patient. I need hardly remind you that plasma loss is the chief feature in burns shock, and that fat embolism and the absorption of products of muscle breakdown are occasional factors in the shock syndrome of injury. But for practical purposes—and the stretcher-side outlook of the field surgical unit and the accident reception ward must be practical —shock is due to loss of circulating volume, and wound shock is due to loss of blood. The treatment of wound shock is the replacement of lost blood by blood: early, before irreparable damage is done; rapidly—that is, at the rate of a pint in 10 to 15 minutes—till the systolic blood pressure has reached 100 mm.; and adequately, till the restoration is within 90% of normal. A wounded man insufficiently resuscitated, or one resuscitated with plasma alone, may have a reasonable pulse and blood pressure, but he is not fitted to stand operation or anaesthetic, to be sent on a journey, or to repel the invasion of bacteria. Fit men recently wounded can take any amount of O (IV) blood from a reliable blood bank;

reactions are seen only where the source of blood is unreliable, or in men who have, after repeated transfusions, developed antibodies against almost any blood but their own.

A transfusion service, with blood banks sufficient to meet any needs, must be available for the resuscitation of the injured and the restoration of the sick in civil life. It will hardly be possible to retain in its entirety that spirit of willing service for others that has bound us together during the war, and many who now attend four or five times a year to give their blood for the wounded will not volunteer with the same readiness in peacetime. Nevertheless if the importance of the service in any scheme of national health is broadcast in the right way, and if the collecting centres are managed with due regard to the time and comfort of those who attend, we need have no fear that the supply of donors will be insufficient for any genuine need. We, on our part, should see to it that transfusion is used freely when needed, but that it is never allowed to become a stunt or an automatic gesture. Since my return to England I have been distressed to see how many surgeons start a blood drip going at the beginning of such straightforward operations as gastrectomy or resection of the rectum. If the value of blood is in replacing lost blood, it should not be wanted during an operation unless severe haemorrhage is expected during its course, as when the patient has a bleeding ulcer or a vascular tumour. The surgeon who expects to lose two pints of blood during a gastrectomy (and a smaller loss does not demand immediate transfusion) should confine himself to circumcision. If the patient is anaemic on admission to hospital the blood deficiency should be fully made up before the operation starts; if during its course he loses more than usual, replacement should, in most cases, be deferred till his reaction to the anaesthetic and operative handling is over and his circulatory requirements can be assessed, calmly and accurately, in the ward.

The need to maintain a positive nitrogen balance during sickness has long been known, but it was not till the publication by van Slyke of a simple copper sulphate method for bedside estimation of plasma proteins that the importance of the study of protein metabolism in clinical medicine received full recognition. The circulating proteins include the antibodies, and they furnish the building material needed for tissue replacement. They are constantly being used, and constantly renewed from proteins in the food. Normal wastage is added to by actual loss in wounds and burns, and when in addition the intake is low, as it is in starvation or during a diet low in proteins as the average invalid diet is wont to be, the protein content of the plasma may sink from its normal 6.7% to not more than half that figure. At this level the whole metabolic machinery is out of gear.

Proteins may be replaced in many ways, of which the simplest is a diet rich in eggs, cheese, and other easily absorbed proteins. In the ill, transfusions of plasma furnish an easy means of replacement. When the need is extreme the intravenous administration of amino-acids can maintain a positive nitrogen balance even in the presence of excessive loss or destruction. By such means some of the victims of the Coconut Grove fire at Boston, who had suffered burns involving more than 50% of their body surface, were kept alive till their skin loss could be made good. More recently the value of intravenous amino-acids in combating liver damage has been shown. At the present time pyrogen-free preparations suitable for intravenous use are scarce and are therefore kept for research purposes, but they will soon be obtainable by all who need them.

Chemotherapy

The value of war as a large-scale experiment in which new methods can be tried and improved is seen particularly in the field of chemotherapy. From a tentative beginning, when we had only sulphanilamide and sulphapyridine and knew little of either, we have progressed by the observation of hundreds of thousands of experiments to a reasoned estimate of the value of both the sulphonamide group and their newer and better-publicized rival, penicillin. No more than a few general observations are possible on this occasion.

Both the sulphonamides and penicillin are bacteriostatic rather than bactericidal. When distributed by the blood stream they reach only those parts which have a blood supply; when applied locally they are effective only in areas they can reach. Neither can therefore be expected to eradicate bacteria lying out of reach of the blood stream and of local attack, as they are in abscess cavities, round foreign bodies, and in the depths of a wound containing dead tissues. Meleney's very careful investigation of 1,700 accidental injuries treated in American hospitals has shown that the sulphonamides, however given, are unable to prevent local infection in a contaminated wound, but that when given by mouth they appear to reduce the incidence of systemic infection. The same may be found to be true to a lesser degree of penicillin. Applied locally, it appears to exert a definite bacteriostatic effect when injected into simple spaces like the meninges, the joints, and the pleura, but its power to sterilize lacerated wounds is by no means proved. In general it may be stated, as Burns has recently pointed out with regard to penicillin, that chemotherapy keeps a local infection local, and will therefore reduce the danger of spreading infection in war wounds and of a systemic flare-up after an operation on infected areas.

Both groups at present have their own sphere. The sulphonamides are cheap, stable, and compact. They can be kept indefinitely and used in any climate, and simple clinical controls alone are needed during treatment. Their disadvantages are the malaise and nausea to which they occasionally give rise, and the dangers of agranulocytosis and renal suppression, which, however, should not occur when the danger is known and guarded against.

Penicillin is a more efficient bacteriostatic than any of the sulphonamides over a wider range. Staphylococci and spirochaetes, against which sulphonamides are ineffective, are particularly sensitive to its action. It appears to bring no dangers, and to be entirely innocuous to human tissues, even in concentrations much higher than any used in clinical work The disadvantages of penicillin are its instability and the elaborate control that is necessary in its use.

At the present moment the sulphonamides are preferred for infections by the *B. coli* group, which are sulphonamide-sensitive but penicillin-resistant; they will therefore usually be chosen for the post-operative treatment of peritonitis and for the pre-operative prophylaxis in such procedures as closure of a colostomy and resection of the colon or rectum. They are the drugs for treatment in the home and in the wilds, and for lesser infections when it is not considered necessary to mobilize the heavy artillery of the bacteriological laboratory. As soon as penicillin can be produced cheaply and in a stable form that can be given by mouth, the sphere of sulphonamides will almost disappear, unless fresh compounds are found which will cover blind spots in the penicillin range.

Penicillin has already written a new chapter in certain infections. In gonorrhoea it has been able, in a 24-hour course, to give a higher percentage of cures than any method of treatment previously known. In syphilis it appears to do the same, but a much longer period must elapse before it can be said that the disease has been cured and not merely suppressed. In the acute osteomyelitis of children it is able, when given early, to eradicate the infection and allow the involved bone to reconstitute its normal architecture. In the surgery of damaged and infected bone it has given what is perhaps the most striking proof of its value. Gunshot fractures have, under the protection conferred by penicillin, been closed by delayed primary suture with a high proportion of success. Gaps following compound fractures have been grafted as soon as, or even before, the wound was healed. Compound fractures have been fixed by plates, and reamputations have been performed while the provisional stump was still discharging. These procedures had been attempted before, but the attempt had usually led to failure or even disaster. That they now succeed is an index of the debt we owe to penicillin.

Old Methods on Trial

If war is a trial ground for new methods it is also able to throw a new light on many old ones. In the last five years the problem of the infected hand has once more come to the fore. A soldier with a wrecked hand can no longer serve as a soldier, and the months of physical and vocational training that have gone to make him one are wasted. When the hand has been wrecked through faulty incisions for the drainage of sepsis the tragedy is one that emphasizes the supreme importance of this branch of surgery in the training of students.

I feel most strongly that the inculcation of correct methods for dealing with infections of the hand is one of the chief tasks of teachers on the surgical side of any hospital. The curriculum is already overloaded. Important subjects such as psychology and radiology are skimped, and new subjects are constantly clamouring for admission. To make room for these I, for one, would gladly remove the whole teaching of operative surgery, including attendance at operations, from the pre-graduate course. The student cannot learn enough in such attendances to be of any value to him; on the other hand, he is present as an unskilled assistant or an unsterile spectator at a performance which should be relegated to a team of skilled experts. He gets a superficial acquaintance with a few operations and does not learn enough to do them himself, but, thinking he has, he may be tempted to try them before he is properly trained.

The ritual of the theatre, and the gradual apprenticeship of undertaking operations of increasing difficulty, should be left to the postgraduate training of those who intend to pass to higher qualifications and to adopt surgery as a career. The student, thus freed, should spend the time at his books or by the bedside, or should watch occasional standard operations from the safe seclusion of an observation floor. But the operative treatment of the infected hand is an exception. The correct operations should be taught to every future doctor; they should be practised on the cadaver and demonstrated in the casualty department. Only so can the hand wrecked by incompetent treatment, by drainage left too late or done through midline incisions for pulp or tendon infections, or by dorsal incisions for infections of the tissue spaces, be avoided. Here I would plead for the final abolition of two methods of drainage still advocated in some books but proved by the extensive experience of war to be disabling. I refer, first, to the horseshoe incision round the pulp of the finger, which after healing leaves a hideous and disabling "frog-mouth" deformity: two lateral incisions meeting across the front of the bone and separated by an intact bridge of skin at the tip give just as effective drainage and leave no disability. Secondly, I refer to incisions into the tendon sheath of the fingers, which, though placed in the correct lateral plane, transgress the joint level: incisions may be made into the sheath for the whole length of each phalanx, but the thin portion which holds the tendon in place at the joint should be left.

Varicose veins provide another common and disturbing problem in the Army. I have come to feel—and most other consultants who see these cases in large numbers agree with me—that the injection treatment has no place in the Services; indeed, I would go further and say the time has come to consider seriously whether the injection treatment of veins has any place in legitimate therapy. For those who would dally on the slippery slopes of cosmetic surgery it has its attractions, for it is a cosmetic procedure and no more. The injection of a prominent vein will cause that vein to disappear, but it does nothing to relieve the back-pressure that made it appear in the first place. The same back-pressure will soon dilate another collateral vein, which will in turn be attacked by the injecter, till finally all veins in the leg, including many of the deep ones, are destroyed and the patient is left with a heavy, aching, and oedematous limb. To-day many of the victims of the injection craze of the 'twenties are coming to the out-patient departments of hospitals seeking in vain for relief.

The only successful treatment for true varicose veins which are causing symptoms is Trendelenburg's operation, properly done. Unfortunately the very simplicity of the operation tempts the cosmetically minded to perform inadequate ligatures through small incisions, and the hangover from injection days tempts him to obliterate the veins in the calf by sclerosing fluids. Unless every collateral in the upper two inches of the saphenous vein is tied—and these may be up to 20—and unless the vein is tied flush with the femoral, recurrence is only too likely. Injection of the calf varices, particularly retrograde injection down the saphenous channel, is a frequent cause of failure, for either the sclerosing fluid is diluted in the varices to a concentration at which it is ineffective or it spreads through the communicating veins and damages those under the deep fascia. Surgical extirpation is tedious, but is the safest and most satisfactory way of destroying these calf varicosities without harming the deeper channels.

Surgeons and Surgical Organization

What of the war surgeon himself—the man we shall know by the British warm, dyed blue, in which he drives around, and by the battle dress he dons for fishing and digging in the garden? What has he learned from his years in the Army, the Navy, the Air Force?

The war has taken men to so many parts of the world, from the frozen mud of Iceland to the scorching sands of Somaliland, and thrown them into campaigns of so many kinds—the shattering horror of Crete or the soul-destroying idleness of the Sudan hinterland—that generalization is impossible. The surgeon who is reasonably fortunate will have served a spell in the forward areas, with a field surgical unit or a casualty clearing station, and he will also have worked at a general hospital at the base or on the lines of communication.

In the forward areas he learns the importance of decision, the need to decide not merely the right procedure but the right time to do it, the realization that there is only one best time for any operation and that, once past, it will never come again. He learns that while a decision may be the right one on the facts as they present themselves when it is made, in the seriously ill or wounded facts are never static but are changing in either direction, so that a course of action that is right at one moment may have to be reversed an hour later. He acquires manual skill, anatomical knowledge far transcending the surgical approaches of textbooks, speed without haste, courage, and physical endurance. He learns to look on the operation as part of a plan of restoration of which it is by no means the most important one, to make allowances for the difficulties of those who have gone before him, and to plan his steps to make the work of those who will follow him easier and more satisfactory. He learns, in the comradeship of the battlefield, to love and respect the patient, Thomas Atkins, who has given all and suffered all, and to resolve all doubts and difficulties by reference to one standard alone—"What is best for this particular man?" He learns, by long periods of work to this high standard, self-respect and self-confidence, without which no surgeon can carry on through the dark days when everything seems to go wrong.

At the base he learns to work as part of a team in his own hospital, as part of a system in the Service of which his hospital forms a part. He finds that he is encouraged to work individually and to put forward his own ideas, but he soon realizes the justice of the control which forbids him to use methods that have been tried and proved dangerous, which discourages him from asking for drugs or instruments as his fancy dictates when the supplies of an army in the field can be made efficient only by some degree of standardization, which gives him every opportunity to study the work of specialist teams so that he shall be able to undertake surgery of every kind should he be put in charge of a unit isolated by time and distance from any help, but debars him from doing intricate operations when others with greater skill and experience and better equipment and assistance are available.

Much that is good in this training and this organization can be applied with advantage to the problems of peace. The chief difference between civil surgery and Service surgery is that the former is based on a loose association of individuals all of whom are free and, in theory at any rate, equal, while surgery in the Services is organized on the principle of the pyramid of responsibilities—a number of experienced surgeons being each responsible for observing, guiding, and encouraging a group of surgeons at a junior level, for co-ordinating their work, and for bringing the lessons they have learned to the notice of those at a higher level. The civil system has the great merit of allowing men of energy and ability to reach the top even though they enter surgery from unorthodox and perhaps despised channels, but it does little to curb or eliminate the incompetent. In the struggle for existence in Nature failures pay for their inefficiency by extinction; but in the free-for-all fight of civil surgery the incompetent and second-rate are unhonoured but are not debarred from practice, in which, if they have a good sales personality, they may be financially successful.

With the advance of technical surgery to the undertaking of feats of greater and greater difficulty, needing not merely the highest technical skill and anatomical knowledge but the design of a plan embracing the whole pre- and post-operative period to eliminate risks that have brought disaster in the past, the difference between the results of the expert and the would-be expert is increasingly apparent. To-day there is nothing to prevent any surgeon on the staff of a hospital—indeed, any man who has secured a legal qualification to practise—from attempting to pin the neck of a femur, resect a carcinoma of the oesophagus, remove a tumour of the brain, or tie a patent ductus arteriosus, without any more valid qualification for the task than boundless self-confidence and a cursory perusal of an article in one of the journals. The system has in the past produced some brilliant surgical freelances; it has also filled innumerable graveyards.

It seems inevitable, in a world where the rights of the individual will be acclaimed in a universal charter, that the individual who is sick must be assured of a service that is, at any rate, above a datum line of adequate competency. It would be folly in the extreme to attempt to limit surgical enterprise by setting certain standards of orthodoxy which must be followed by all. But it would be less than justice to the patients for whom we stand responsible to allow free rein to the enterprise of the type of surgeon known as courageous—courage in this context meaning willingness to face any risk so long as it is borne by the patient. We must insist that no man shall undertake any of the more hazardous operations till he has been trained for it by apprenticeship in simple tasks, till he has studied its steps in the clinics of acknowledged masters, and till he has practised it under supervision.

The pyramid of responsibility must be the key to our surgical organizations—not the hard and static Pyramid that stands on the Nile as a monument to past oppression, but the human pyramid that forms the finale at the circus, where the man at the top, who is usually the father, is hoisted up and supported by a willing phalanx below, where he feels the stresses of each member transmitted to him and encourages or chides as the performance of the night demands, but where, at the end, he brings all forward to take the bow.

AN OUTBREAK OF HEPATITIS IN A DIABETIC CLINIC

BY

HUGO DROLLER, M.D.Munich, M.R.C.P.Ed.

Clinical Assistant, Medical Department, Royal Hospital, Sheffield

From Jan., 1943, until Jan., 1945, 63 diabetic patients attending the clinic at the Royal Hospital, Sheffield, have been diagnosed as suffering from hepatitis. The clinic supervises approximately 450 patients of all ages; elderly females preponderate.

Prodromal Symptoms

Anorexia, loss of weight, and vomiting were often encountered. Vague abdominal pains set a diagnostic problem until the full clinical picture developed. Tingling of fingers and neck rigidity may have been early neurological manifestations (Lescher, 1944). Enlargement of the liver, with tenderness, was noted in 30 patients. The organ was firm, the edge blunted and tender. Splenic enlargement was evident in three patients. In one the spleen was felt 2 in. below the costal margin; in the other two the tip could be felt. Two patients showed macular skin rashes 24 hours before the jaundice appeared and 11 had stiffness of joints.

Tingling in fingers and neck rigidity	2
No symptoms	2

Course and Complications

Immediate complications occurred in a number of cases owing to the sudden disturbance of carbohydrate metabolism. The disturbance was akin to that seen in diabetics suffering from any infectious disease. The lowering of carbohydrate tolerance and ketosis occurred mainly in younger people, and were temporary. Insulin had to be increased and the diets altered to suit patients who had no desire for food.

Another complication was acute atrophy of the liver. Two patients died from this. One patient showed acute shrinkage of the liver one day after the jaundice became manifest. She recovered, but the severity of the diabetic state has permanently increased, and instead of 60 units of insulin she now requires 120 units. Apart from this she has kept well for the last 18 months.

Delayed complications occurred in 8 cases. They were associated with the persistence of the jaundice for some time and the transition from acute to chronic hepatitis. Two patients died. The 6 who are alive are in various stages of ill-health.

TABLE III.—*Deaths and Cases of Chronic Hepatitis*

Case	Age	Duration of Jaundice	State of Health
1	27	7 days	Died. Acute yellow atrophy (confirmed at P.M.)
2	56	16 „	Died. Subacute atrophy (confirmed at P.M.)
3	73	240 „	Died 300 days after onset of jaundice. Cirrhosis of liver. No P.M.
4	64	90 „	Died 110 days after onset. Cirrhosis of liver (confirmed at P.M.)
5	62	180 „	Severe ascites; 190 pints removed so far
6	67	90 „	Liver no longer palpable. Anorexia. No free fluid
7	65	300 „	Liver 1 in. below costal margin. Anorexia
8	65	105 „	Liver no longer palpable. Liver function tests remain abnormal. Feels quite well
9	67	120 „	Liver 2 in. below costal margin. Anorexia
10	58	110 „	Anorexia; backache. Liver small and nodular (confirmed at laparotomy). Ascites and oedema of legs absorbed

Patients suffering from chronic hepatitis showed little disturbance of carbohydrate metabolism. They all required small doses of insulin before the onset of hepatitis, and continued with them afterwards. There was neither ketosis nor excessive glycosuria.

There appears to be a relation between duration of jaundice and failing liver function. There is also a direct relation between the age groups and the duration of jaundice.

TABLE IV.—*Age and Duration of Jaundice*

Age	Duration in Days									
	10	20	30	40	50	60	70	80	90	100+
–9	1									
10–19		1	1							
20–29	1		1	1	1	1				
30–39		1	2	2						
40–49			4		1	2				
50–59		4	3	3	2		1	1		
60–69		1	2	3	5	2	1	1	2	6
70+			2	2			1			1

In 49 cases jaundice cleared in under 2 months, with an average duration of 33 days. Six patients in whom the jaundice lasted for 3 to 8 months have apparently recovered completely, 6 are still ill, and 2 died after 300 and 110 days' illness respectively.

It is noteworthy that all the chronic hepatitis cases and all but one of the deaths occurred in persons over 55 years of age. The age and sex incidence of cases (Table V) shows a preponderance of older patients, and it is possible that age as well as diabetes played a part in producing the high incidence of fatalities and chronic hepatitis.

Table V.—*Age and Sex Incidence*

Age in Years:	0–	10–	20–	30–	40–	50–	60–	70–	80+	All Ages
Male ..	1	—	4	3	2	—	6	1	—	17
Female	1	2	3	3	4	13	16	3	1	46
Total ..	2	2	7	6	6	13	22	4	1	63

Method and Spread of Infection

The cases of hepatitis might have been due to infective hepatitis spreading by contact among patients attending the clinic or to homologous serum hepatitis (Ministry of Health Memo, 1943) spread by syringes used for collecting blood. Certain data are presented and analysed in order to investigate these possibilities.

Organization of the Clinic.—It has been the practice of this clinic to let the patients attend periodically. They arrive in the fasting state in a large out-patient hall, and sit on benches, which are usually overcrowded on clinic mornings (60 to 70 patients may attend). They queue slowly to have their weights recorded and then have venous blood drawn for blood-sugar estimations. The sister in charge of the collection of blood draws it, using a fresh needle on each patient. The needles are boiled for 20 minutes. The syringes are never boiled, but are kept in spirit and rinsed in sterile water before use. The patient returns to the out-patient hall, perhaps getting some tea from the buffet, has his breakfast, and awaits the medical interview. Thus there were opportunities in the clinic for spread either by contact or by syringes.

Monthly Incidence of Cases.—Table VI shows the number of cases occurring in each month from Feb., 1943, to Dec., 1944. The incidence increased in June, July, and Aug., 1943, decreased during the next three months, and rose to a sharp peak in Dec., 1943.

Table VI.—*Monthly Incidence of Cases*

	J.	F.	M.	A.	M.	J.	J.	A.	S.	O.	N.	D.	Total
1943 ..	—	2	1	1	3	5	6	6	4	4	3	11	46
1944 ..	2	—	1	1	2	2	1	3	3	—	—	2	17

Owing to the irregularity of attendance, and consequently of contacts between cases, no conclusions as to the method of spread of infection can be drawn from the monthly incidence.

Contact Between Successive Cases.—The possibilities of contact between cases were studied on a chart of attendances at the clinic. It was assumed that cases were infectious during a fortnight before and a fortnight after the onset of illness. In 7 cases the incubation period might have been 20 to 40 days, and in 23 others it might have been 41 to 120 days. In 4 cases the incubation period might have been either 20 to 40 or 41 to 120 days. Thus 11 cases could be accounted for on the basis of the 20–40-day period found in infective hepatitis, and 23 cases on the 41–120-day period found in homologous serum hepatitis. The latter number might have been increased by assuming a longer period of infectivity in the infecting case. Thus, in just over a third of the cases there was a possibility that the incubation period was that which usually follows parenteral administration of icterogenic serum (Havens, Paul, and van Rooyen, 1945). On the other hand, there were 7 cases in which the incubation period might have been 20 to 40 days, and it is impossible to dismiss completely the idea that some of the cases may have been due to contact-spread of infective hepatitis.

Similar conclusions are suggested by two instances of apparent spread to contacts who did not attend the diabetic clinic.

1. Girl aged 17, admitted in pre-coma. Jaundice appeared next day. A nurse in charge of this patient came down with a sharp attack of hepatitis 30 days later; it lasted three weeks. The nurse had a bad relapse lasting several months.
2. Man aged 26, admitted with hepatitis and ketosis. His wife developed jaundice 51 days later.

The incubation period in the first case suggests that the disease was infective hepatitis, while the second is perhaps another instance of the long incubation period occasionally observed in the contacts of cases of homologous serum hepatitis (Propert, 1938; Beeson, Chesney, and McFarlan, 1944; Neefe *et al.*, 1944).

Two patients were possibly infected at home.

1. Mrs. A., aged 66; lives with her married daughter. Her son-in-law had jaundice in mid-June, her daughter in early August, she herself 27 days later.
2. Mrs. B., aged 63; nursed her daughter, who had jaundice. She developed it 56 days later.

Mrs. A.'s was almost certainly a case of infective hepatitis, while Mrs. B. might have been infected by a missed case at home or by contact or syringes in the clinic.

The epidemiological picture of this outbreak was complex, and it appears that both contact and syringe transmission occurred. There were no instances of second attacks to suggest the activity in this epidemic of two immunologically distinct icterogenic agents, and the data available suggest an identity rather than a difference between the agents of infective hepatitis and homologous serum hepatitis. This may, however, apply only to the present epidemic, because other workers have recorded data suggesting differences between the agents (Witts, 1944; Beeson, Chesney, and McFarlan, 1944).

Discussion

Graham (1938) published the first account of an epidemic of jaundice in a diabetic clinic. He saw 28 cases in two and a half years. Overcrowding, considered one of the important contributing factors, was abolished and the epidemic quickly subsided. Cameron (1943) and MacCallum and Bradley (1944) showed that the virus of infective hepatitis could be transmitted by intravenous injection of icterogenic serum taken from a case during the pre-icteric stage and the early days of the jaundice. The present epidemic occurred at the time of a high incidence of the disease among the general population. There was also some overcrowding, which was intensified by the queueing for weighing and bleeding. As the blood was collected in syringes which were not boiled, it is possible that small amounts of infective material might contaminate the needles (MacCallum and Bauer, 1944; Cameron, 1943; Salaman *et al.*, 1944). The sister in charge of bleeding also gave injections at the V.D. clinic. There was no transfer or exchange of syringes between the two clinics, which are in different parts of the hospital.

In view of the possibility that infected syringes were the cause of the epidemic, all routine blood-collecting was stopped after Sept. 1, 1944, and only special cases were bled. The number of blood samples was thereby reduced from 50–70 to 5–8. The technique of drawing blood has not been changed. Since then only one case has appeared after an interval of 93 days. With the abolition of routine blood-collecting, overcrowding also diminished and, one supposes, the coincident droplet infection with it. There was less waiting and queueing, and the patients did not stay quite as long, because they took their breakfast at home.

The unusually high death rate and incidence of chronic cases compared with other outbreaks compels one to consider whether dietary factors came into play (Cullinan, 1939; Snapper, 1941; György and Goldblatt, 1942; McLean, Ridout, and Best, 1937; Aylward and Holt, 1937).

Since the advent of the slow-acting insulins the diabetic diets have been steadily increased. The diets used at this clinic are not high-carbohydrate diets in the strict sense. According to severity, age, and occupation, 120 to 200 g. of carbohydrate is taken each day. The diabetics who contracted jaundice had made use of their special meat and fat rations. They received 70 to 100 g. of protein and 100 to 150 g. of fat. Family rations were encroached upon by all the patients questioned. There is, in fact, no evidence to show that in these diabetics liver damage could be caused by dietary restriction or excess alone. On the other hand, there seems to be no doubt that insufficient diets may protract and aggravate liver damage caused by hepatitis. In the elderly diabetics who developed chronic hepatitis food intake had been poor and nutrition had suffered accordingly.

Summary

An outbreak of hepatitis in a diabetic clinic extending over two years and involving 62 patients is described. There were 4 deaths, and 6 patients were left with evidence of residual liver damage.

My thanks are due to Dr. C. G. Imrie, under whose care the patients were at the diabetic clinic, for permission to publish this paper; to Prof. L. J. Witts for much helpful criticism; to Dr. H. J. Barrie for permission to quote from his post-mortem reports; and to Dr. A. M. McFarlan for his help with the section on the method of spread of infection.

TRANSMISSION OF INFECTION DURING WITHDRAWAL OF BLOOD

BY

K. MENDELSSOHN,* M.A., Ph.D.

AND

L. J. WITTS, M.D., F.R.C.P.

(From the Nuffield Department of Clinical Medicine, Oxford)

It is now generally realized that jaundice may be transmitted by syringes used for intravenous therapy if the syringes are merely rinsed with sterile water between cases and not sterilized by heat. Bigger (1943) showed that it is extremely difficult to sterilize a syringe by rinsing it even with antiseptics, and Salaman and co-workers (1944) reduced the incidence of jaundice in a V.D. clinic to vanishing-point by using properly sterilized apparatus for each individual patient. It is not so generally appreciated that there is almost equal risk of transmitting disease by syringes used for venepuncture. Sheehan (1944) attributed a long-drawn-out epidemic of jaundice in a sanatorium to transmission by the syringes used for taking blood for erythrocyte sedimentation rates, and in the present number of the *Journal* (p. 623) Droller records an outbreak of jaundice in a diabetic clinic which appears to have been in large part due to transmission by the syringes used for obtaining venous blood for estimation of blood sugar.

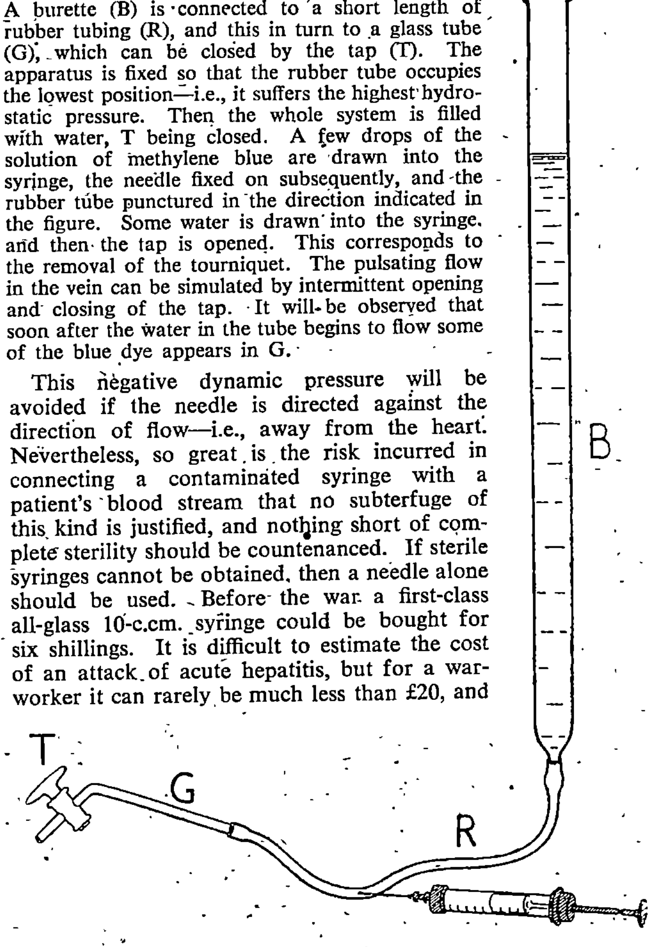
The orthodox method of taking a venous blood sample with a syringe consists in first placing a tourniquet on the upper arm to produce venous distension and then puncturing a vein at the bend of the elbow, inserting the needle in the direction of the heart. Blood enters the syringe under pressure from the vein, and a sample is taken by gently withdrawing the plunger. When the desired amount is collected the tourniquet is released and the needle withdrawn from the vein. Throughout the procedure direct contact with the vein is established by means of the sterile needle only, and since during the whole operation the pressure in the vein has been higher than that in the syringe it is assumed that no flow of blood can have taken place from the syringe into the vein.

In Droller's clinic the same syringe was used for all the patients bled on any one morning. It was washed out between cases and the needle was changed. It may appear strange that infection should have occurred through the syringe, though there is obviously a possibility that, unless great care is taken in changing needles, some of the contents of the wet syringe may be forced up the lumen of the needle and contaminate the point. But even if every precaution is taken in fitting the needle, some of the contents of the syringe not only can but *must* be discharged into the patient's vein during the venepuncture, and therefore material must inevitably be transmitted from one patient to another if the syringe is communal and unsterilized. This can very easily be proved by deduction or experiment.

The hydrostatic pressure of a fluid is equal to the actual pressure only if the fluid is at rest. Apart from its hydrostatic pressure, a fluid in motion exerts also a *dynamic* pressure, which depends on the speed and the direction of flow and which can have positive and negative values. In venepuncture the tourniquet must be released before the needle is withdrawn, to avoid the formation of a haematoma, and this is the determining factor in the transmission of infection. The operator ceases to exert traction on the piston of the syringe at this point, particularly if he is working single-handed. A flow of blood takes place in the vein when the tourniquet has been released, and this flow occurs in the direction in which the injection needle points—i.e., it causes a *negative* dynamic pressure in the opposite direction. As soon as this negative dynamic pressure attains a higher value than the static-pressure difference between vein and syringe, blood must flow from the syringe into the vein. In other words, the flow of blood in the vein sucks some of the contents of the syringe into the vein against the static-pressure head, very much as the contents of a throat spray are drawn up into a passing stream of air. It is clear that if the syringe was contaminated the contaminant will be drawn into the vein together with blood from the syringe.

The effect of the negative dynamic pressure can be demonstrated by substituting for the vein a tube filled with water, and for the contaminant a concentrated solution of methylene blue (see Fig.) A burette (B) is connected to a short length of rubber tubing (R), and this in turn to a glass tube (G), which can be closed by the tap (T). The apparatus is fixed so that the rubber tube occupies the lowest position—i.e., it suffers the highest hydrostatic pressure. Then the whole system is filled with water, T being closed. A few drops of the solution of methylene blue are drawn into the syringe, the needle fixed on subsequently, and the rubber tube punctured in the direction indicated in the figure. Some water is drawn into the syringe, and then the tap is opened. This corresponds to the removal of the tourniquet. The pulsating flow in the vein can be simulated by intermittent opening and closing of the tap. It will be observed that soon after the water in the tube begins to flow some of the blue dye appears in G.

This negative dynamic pressure will be avoided if the needle is directed against the direction of flow—i.e., away from the heart. Nevertheless, so great is the risk incurred in connecting a contaminated syringe with a patient's blood stream that no subterfuge of this kind is justified, and nothing short of complete sterility should be countenanced. If sterile syringes cannot be obtained, then a needle alone should be used. Before the war a first-class all-glass 10-c.cm. syringe could be bought for six shillings. It is difficult to estimate the cost of an attack of acute hepatitis, but for a war-worker it can rarely be much less than £20, and for a trained soldier it must be much more. It is therefore penny wise and pound foolish to economize in sterile syringes; but false economy of this kind is still much too prevalent in civil and military clinics and hospitals. The infecting dose of the virus of infective hepatitis is probably of the same order of size as some of the larger protein molecules, and a little contamination with this virus can go a very long way. A venepuncture, whether for taking blood or injecting drugs, is a minor operation, and there is no excuse for any lapse from the classical principles of sterility.



---

* With a grant from the Medical Research Council.

Summary

When blood is taken from a vein with a syringe by the orthodox technique some of the blood is sucked back into the vein when the tourniquet is released. If, therefore, the syringe is not sterile the patient is exposed to infection.

IRON-DEFICIENCY ANAEMIA IN NORTH-WEST INDIAN SOLDIERS

BY

MARTIN HYNES, M.D., M.R.C.P.
Major, R.A.M.C.

MOHAMMED ISHAQ, L.S.M.F.
Capt., I.A.M.C.

AND

T. L. MORRIS
Sergeant, R.A.M.C.

(From the Anaemia Investigation Team, India Command)

Little work has been done on iron-deficiency anaemia in India, and that entirely on the rice-eating labourer. Although anaemia is universal in this class (Macdonald, 1939; Napier and Das Gupta, 1942), it is scarcely improved by iron (Napier and Das Gupta, 1936; Bhave and Bopaiya, 1942). Even heavy hookworm infestation does not always increase anaemia in these people, although labourers with severe anaemia, whether macrocytic or microcytic, are more commonly heavily infested than their fellows (Napier and Billimoria, 1937; Napier and Das Gupta, 1937; Napier and Majumdar, 1938; Hare, 1940). The discovery, reported in this paper, of widespread mild iron-deficiency anaemia in North-West Indian soldiers is therefore of some interest.

Material and Methods

This work was carried out in the district of Peshawar (North-West Frontier Province) from Feb. to June, 1944. Some 1,400 men from six regiments were examined. All were natives of North-West India, and included Sikhs and Mohammedans from Patiala; Mohammedans, Jats, and Hindus from Rajputana; Mohammedans, Sikhs, Jats, and Gujars from the Punjab; and Pathans. The men were unselected, and all were regarded by their units as fit for active service. All had served more than one year, and two-thirds were in their second or third year of service.

Only the capillary blood haemoglobin of most of the men was estimated, but full haematocrit determinations were done on venous blood from 341 men. These latter were selected according to their (capillary blood) haemoglobin values, with weighting of the higher and lower haemoglobin classes; but they were in all other respects representative of the whole group.

Blood, whether from finger or vein, was drawn without stasis; Wintrobe's dry oxalate mixture was used for venous blood. Haemoglobin was estimated as acid haematin; the Zeiss haemometer, which has a glass wedge standard, was used, recalibrated to a maturation time of 20 minutes. (This instrument was calibrated against van Slyke blood-oxygen-capacity determinations in London in 1939. The only comparison available in India in 1943 was with various Adams and Hellige haemoglobinometers; there was good agreement.) Adams haemoglobin pipettes were used. For red cell counts, two Zeiss-Thoma chambers were charged from the same pipette, and about 500 cells counted on each; if the totals for the two chambers differed by more than 10% a new pipette was filled and the count was repeated. Adams and Zeiss red-cell-counting pipettes were used. The packed cell determinations were done in Wintrobe haematocrits; 45 minutes' spinning at about 3,000 revolutions a minute gave a constant reading.

Stools were examined for hookworm ova by the usual gravity flotation technique, in which about 1 g. of faeces is suspended in 10 ml. saturated saline. The number of ova per microscope field (1/3-in. objective, × 6 ocular) was counted, and the infestation roughly classified as very light (1 egg per 6 or more fields), light (1 egg per 2–5 fields), moderate (1–4 ova per field), or heavy (more than 5 ova per field).

Results

Table I.—*The Distribution of Hb Values (Capillary Blood) among North-West Indian Soldiers*

	Haemoglobin (g. per 100 ml.)											Total	Mean	σ
	6–	7–	8–	9–	10–	11–	12–	13–	14–	15–	16–			
No. of cases ..	1	2	5	13	43	131	256	417	361	113	14	1,356	13·42	1·371
Per cent. ..	0·5			1	3	9·5	19	31	27	8	1			

The capillary blood haemoglobin distribution is shown in Table I. No significant difference was found between units, religions, or castes. Only one-third of the men had over 14 g. haemoglobin per 100 ml.; 14% had less than 12 g., and 5% less than 11 g.

13–	77	13·5	4·9	0·38	45	2·20	91	6·53	30·2	1·49
14–	82	14·4	5·2	0·32	47	2·35	90	5·46	31·0	1·47
15–	51	15·4	5·4	0·31	49	2·01	91	5·51	31·3	1·35
16–	17	16·4	5·5	0·19	51	1·90	93	4·03	32·0	1·33

The results of the blood counts and haematocrits on venous blood are summarized in Table II. All the anaemia was hypochromic, and usually normocytic. Of bloods with less than 11 g. haemoglobin about one-third were microcytic [mean corpuscular volume (M.C.V.) less than 75 c.μ]; of those with 11–11.9 g. about one-sixth were microcytic; and all but three of the remaining bloods were normocytic. No case of macrocytic or dimorphic anaemia was found. Table II shows how little the red cell count fell with decreasing haemoglobin until values under 10 g. were reached. The disproportion between the red cell count and the haemoglobin was sometimes extreme: 5 men with haemoglobins of between 9 and 11.9 g. had red cell counts of 6 millions per c.mm. or more; their M.C.V.s were 60–70 c.μ. (Such bizarre counts were of course repeated.)

The steady fall in the haemoglobin concentration or M.C.H.C. (= mean corpuscular Hb concentration) (see Whitby and Britton's *Disorders of the Blood*, Chapter III) as anaemia increased is evident in Table II. (The correlation coefficient between haemoglobin and M.C.H.C. is 0.73, about 14 times its standard error.) The differences between the mean M.C.H.C.s in different haemoglobin classes are statistically significant, except between the 14- and 15-g. classes. The mean M.C.H.C. of the 16-g. class is, however, significantly higher than that of the 15-g. class ($D/\sigma_D=2.0$) and the 14-g. class ($D/\sigma_D=2.9$).

These findings suggested a widespread iron deficiency, possibly extending even to some of those with 14 and 15 g. haemoglobin per 100 ml.

The mean values in the 14–16 g. haemoglobin classes are reasonably close to those obtained by Napier and Das Gupta (1936) for 30 young well-to-do Indian males in Calcutta. (Their means and standard deviations were:—Hb, g./100 ml.: 15.7, 0.91; R.B.C., M./c.mm.: 5.53, 0.49; M.C.V., c.μ: 90.5, 7.9; M.C.H.C., %: 31.1, 1.2.)

Response to Iron Therapy

The only unequivocal proof of iron deficiency is an increase in the haemoglobin following iron therapy. A group of these soldiers was therefore given 20 gr. of ferri sulphas exsiccatus daily—58 for 21 days, and 17 for 14 days. (The object was not completely to cure anaemic men, but to observe what proportion responded to a massive dose of iron.) The powder was suspended in distilled water (10 gr. to 1/2 oz.) immediately before use, and a member of the team gave each man a dose of the mixture morning and evening, and watched him swallow it.

Nearly all the men complained of diarrhoea (up to six motions daily) for the first two or three days of medication, but this symptom soon disappeared without any change of dosage. By the third week complaints of mild digestive upsets and constipation were faily common, but no man felt unwell enough to suggest discontinuing his medicine. The majority of the men felt better after the course, but, to some, stomach troubles outweighed any possible improvement in their general health.

The blood investigations were repeated the day after the iron course ended; the blood pictures before and after treatment are summarized in Tables III and IV. Most of the anaemic men had improved greatly: the best haemoglobin rise was from 9.6 to 15.5 g. after 21 days' treatment. An increase of over 0.5 g. haemoglobin per 100 ml. was outside the experimental error of the haemoglobinometer used, and was regarded as significant. By this criterion two-thirds of the 14-g. class and one-half of the 15-g. class responded to iron therapy (Table V).

TABLE III.—*Showing the Average Response of Different Hb Classes to 21 Days' Iron Therapy. (I=Before Treatment; II=After Treatment)*

Hb Class	No. of Cases	Hb (g.)		R.B.C. (M./c.mm.)		Haematocrit		M.C.V. (c.μ)		M.C.H.C. (%)

15–	2	15·5	15·9	5·3	5·7	49	49	93	86	32·0	33·0
16–	2	16·3	16·5	5·6	5·4	50	49	90	91	32·6	34·1

TABLE V.—*The Number of Men in Each Hb Class treated with Iron, and the Number showing a Hb Increase of Over 0.5 g. per 100 ml.*

Haemoglobin Class (g. per 100 ml.)	<11	11–	12–	13–	14–	15–	16–
Number of cases ..	9	7	9	20	18	8	4
Number responding	9	6	8	8	10	4	0

If the proportion of responses in each haemoglobin class be fitted to the population distribution (Table I), we may conclude that about 60% of the population were iron-deficient.

Hookworm infestation had no unfavourable influence on the response to iron; indeed, three-quarters of the infested men responded, compared with one-half of the uninfested. The difference was not entirely due to the greater proportion of more anaemic men among the infested, but it was not statistically significant. Three anaemic men did not respond to iron. Of these, two were normal to clinical examination and had no hookworm infestation; the third had had recurrent diarrhoea and sore tongue for 18 months. (These men are included in Table III, and somewhat reduce the average improvement.)

Hookworm Infestation and Anaemia

The most common cause of iron deficiency in the Tropics is hookworm infestation. The infestation rates in different units in this series varied from 6 to 53%. Of the whole series, 12% had very light infestation, 8% light, 8% moderate, and 1% heavy. Table VI shows the haemoglobin distribution in men with the different degrees of infestation. The mean haemoglobin level of men with even very light infestation was significantly lower than that of those with none; and the mean fell still further as the weight of the infestation increased. Of the men with no infestation, one-half had over 14 g. haemoglobin per 100 ml., and only 13% had less than 12 g.; whereas of the men with moderate infestation, one-half had less than 12 g. haemoglobin, and only 15% had over 14 g.

TABLE VI.—*Showing the Relation between the Hb (Venous Blood) Distribution and Hookworm Infestation in North-West Indian Soldiers*

Hookworm Load	Haemoglobin (g. per 100 ml.)										Total	Mean	σ	
	7–	8–	9–	10–	11–	12–	13–	14–	15–	16–				
None*	2	2	3	3	22	29	64	67	42	16	250	13·83	1·632	a
Very light	1	—	—	5	5	12	12	5	7	2	49	13·13	1·793	b
Light ..	1	1	1	4	7	6	2	5	3	—	30	12·30	2·042	c
Moderate	1	2	3	6	1	7	2	4	—	—	26	11·54	2·029	d

D/σd:—ab 2·5; bc 1·8; cd 1·4; bd 3·4.

The above figures show that hookworm infestation was an important cause of this anaemia, but it was not the sole cause. Nearly one-third of the men with less than 11 g. haemoglobin per 100 ml. and over one-half of those with 11–12.9 g. had no demonstrable infestation.

The Iron Intake

The ration diet of these soldiers is nearly vegetarian, with a very small daily allowance of meat. The staples of the diet are ata and dal, and the important iron sources are:

Ata (coarse wheat flour)	50 mg. iron daily
Dal (pulses)	10 mg. „ „
Greens (in season)	5 mg. „ „
Meat	1 mg. „ „

It will be seen that there is theoretically a liberal amount of iron in the diet, but only 1 mg. of this is derived from the meat.

Discussion

A survey of an adequate number of North-West Indian soldiers revealed widespread mild anaemia—two-thirds had less than 14 g. haemoglobin per 100 ml. This anaemia was all hypochromic, and either normocytic or, less commonly, microcytic. The response to iron therapy showed that nearly all the anaemia was due to iron deficiency, and suggested that over half the men with 14–15.9 g. haemoglobin were not saturated with iron. Cases of moderate and severe anaemia were usually (but not invariably) associated with hookworm infestation, and milder cases usually were not. Even the men with the lightest infestation had a mean haemoglobin level significantly lower than that of non-infested men.

There was no other source of blood loss, so that those cases of iron-deficiency anaemia not due to hookworm infestation must be ascribed to an inadequate iron intake. The daily iron-intake was at least 60 mg., but all except 1 mg. of this was derived from vegetable sources. It would appear that the greater part of this dietary iron was not assimilated, for the response to iron therapy proved that the men were definitely iron-deficient in spite of the high iron content of the diet. (Little work has yet been done on the effect of phytic acid and mineral imbalance on the absorption of iron from cereal diets such as these men ate.)

These men, living on the threshold of dietary iron deficiency, are naturally very readily made anaemic by even the lightest hookworm infestations—infestations which would scarcely affect men with adequate iron reserves and intakes.

Summary

Widespread mild anaemia was found among North-West Indian soldiers.

The blood findings suggested that this was iron-deficiency anaemia, which was proved by showing that it responded to iron. By the same test, many men with normal haemoglobin levels were not saturated with iron.

Most of this mild anaemia was not associated with hookworm infestation.

Men with even very light hookworm infestation had a lower mean haemoglobin level than non-infested men, and most men with a moderate degree of infestation were anaemic.

In the absence of any cause of chronic blood loss in most of the men, it is concluded that the major cause of this anaemia is a deficient iron intake.

The daily food ration of the Indian soldier contains over 60 mg. iron, but of this all except 1 mg. is derived from vegetable sources. It is concluded that the greater part of this iron is not assimilated.

These men, who may develop iron-deficiency anaemia due simply to dietary deficiency, are unduly susceptible to hookworm anaemia.

Our thanks are due to the many officers, both medical and combatant, whose help made this work possible; and to the Director of Medical Services in India for permission to publish this paper.

"ECZEMA AUTOLYTICA"

BY

S. WATSON SMITH, M.D., F.R.C.P.
Consulting Physician, Royal Victoria and West Hants Hospital, Bournemouth

The term I use can be defined as a skin reaction culminating in an acute eruption of scattered vesicles: breaking out rapidly on forearms, neck, face, and trunk from above downwards, in that order; following in point of time late after a persisting dermatitis or ulceration or patch of varicose eczema in the leg or ankle region, more often than elsewhere; standing as secondary in relation to the one or the other, and as the outcome and sequel. Of a sudden, the primary eruption becomes tender, dry, red, and sharply inflamed, from neglect by the patient or from unsuccessful treatment, so exciting at a distance by way of the blood stream a secondary, autolytic eczema of constant character and uninfective kind, usually beginning on exposed parts, then spreading to covered parts.

The Lesion and Distribution

The vesicle characterizes this autolytic eruption, arising as an erythema about the papillary vessel-loop in the skin, speedily becoming a papule, then a vesicle. Some degree of oedema of the adjacent skin accompanies the vesiculation; there is no urticarial reaction.

At first the vesicles break out on the flexor forearms, sparingly on the sides of the neck and face, and on the trunk in its upper parts—not in patches, but, when fully developed, as a uniform eruption of discrete, scattered pink vesicles deep-seated in the skin, in area unmarginated, without figured pattern but with an uneven bilateral symmetry. Coincident with this outbreak, vesicles erupt about the primary patch; which patch, in its behaviour, offers the clue to the pathogenesis, and points the ready remedy for the secondary eczema. Owing to the limb being dependent, the vesicles in leg or ankle are of venous tint; in disease of the right side of the heart the whole secondary eruption is of a constant cyanotic hue, not pink.

The Cause

To what can this eruption be ascribed? The starting-point lies in a long-standing ulceration or circumscribed dermatitis of the leg or arm that has refused to heal in weeks or months, or after a year or two; the actual cause turns upon this delayed healing. The patient usually has for long laboured in vain with treatment by unsuitable applications, loose bandaging, and without necessary rest in bed. The original patch, vitiated by time and mixed infection, is usually found to have been treated by the mistimed use of a dry non-absorbent tissue dressing secured by one or two turns of a bandage; an aniline dye or silver nitrate paint; a too strong impermeable ointment; or a dusting powder. Any one or sequence of these, used prematurely in the course of the primary dermatitis, has the power to excite dermolysis by occlusion. A dermolysin is thereby formed locally: a foreign protein of bacterial origin or, more likely, a tissue-breakdown product—one or other, or both acting in concert—that sensitizes the patient to his own exudate and is the trigger that fires the systemic outbreak. This, in its changed form, is absorbed into the blood stream, circulating to the terminal capillaries of the skin, there to be slowed down and subjected to quick, sensitive variations in local temperature and exposed to other physical influences. Perhaps this is a sufficient explanation of the nature and distribution of the eruption. At all events, the lysin is of toxic origin, blood-borne; that much seems certain.

It is generally accepted that autolytic eczema has a constitutional cause to dispose to it, with a closer exciting cause in an auto-intoxication, rather than a micro-organismal toxaemia, arising locally in the patch. Clearly, the oedemato-vesicular eruption is a superficial non-microbic affection of the skin in areas guided and determined by the vessel route taken by the causal agent mentioned, always in the direction first of the uncovered parts. The constant aspect and locality of the autolytic eruption gives the denial to any suggestion of contagion carried by fingers or fomites; spread can happen only by absorption of autotoxin, and to a chosen site in the circulation. The autotoxic agent cannot be identified by present-day tests; it is certainly not lethal. An analogous case is the trichophytide—a generalized eruption found in the occasional patient with ringworm of the glabrous skin; a truer analogy is with the tuberculides; another perhaps, though less true, with the eczematides. Autolytic eczema has, however, an origin, character, and independence of its own and, taken in time, is readily curable by eliminating the cause.

The Main Features

In any skin disease it is advisable to examine the whole cutaneous surface, never to omit examining legs and feet, for it sometimes happens that the patient thinks the doctor unlikely to be interested in her "old leg." An incomplete or missed diagnosis will miscarry only to increase the patient's suffering, threatening greater severity and a continuance of the disease, with added difficulty in its control.

In autolytic eczema the signs are those of a systemic affection The patient is usually ambulant, a woman, the average age of occurrence 50 years; and the lesions may erupt to reach their peak even in so short a time as seven days. The course of the eruption is this: a primary dermatosis in a lower limb from an infected confined dermatitis, ulcerative or other, below the knee; this had begun with an overlooked or neglected trauma, however small, such as a scratch, a burn, or the pulling out of a hair, to breach the surface; and, being still unhealed, is followed in an average of nine months by a secondary eczema erupting in the positions described, the earliest crop of vesicles occurring on the forearms. Autolytic eczema is not seen in extensive acute dermatitis in the leg, but only where the area affected is comparatively small and lasting; in so-called "eczema rubrum" and the moist-surfaced "eczema madidans," both more or less acute or subacute in their behaviour, the disease is not seen.

Subjective symptoms are much complained of: hot tense skin, almost intolerable itching, loss of appetite with furred tongue, malaise, distress of mind, insomnia. The patient is apyrexic, and shows no characteristic changes in the blood that can be discovered by tests at present known. Perhaps these facts can be taken to mean failure of immunity response as is believed to happen in protracted disease that is localized. In this case the autolytic eczema develops unchecked. The patient feels ill, depressed, and miserable, chiefly from the subjective discomfort and unhappy self-consciousness created by the disfigurement of face and neck by oedema and vesicles, as well as the fear of infecting others. Itching precedes the outbreak of the autolytic eruption to give warning of its coming, usually worst in the areas about to erupt, but by and by becoming widespread and paroxsymal in attack. The visible eruption begins in an acute phase superimposed locally on the primary focus of inflammation; the secondary eczema follows on, passing through an initial stage of pruritus to papulation, then full efflorescence in an oedemato-vesicular eczema, far distant from its source. Clinically, this progression can be observed in its orderly sequence.

The secondary autolytic eruption bears no resemblance to the original leg or ankle inflammation out of which it arises. The primary patch becomes red and painful, pervaded by a mixed pyogenic infection, and has come to a standstill in the healing. Is it this changed excited dry state of the patch which determines the formation and absorption of a transmuted and toxic agent there, which calls out the autolytic eczema in its acuteness, sometimes to come and go afterwards in a subacute way?

Treatment: The Plan

Treatment, preventive and curative, must first be directed towards the primary source of the disease: here is the key to success. Once established, the autolytic eczema will refuse to go until this is healed. To prevent the secondary eczema, the use of moist permeable absorbent dressings, changed often till the surface has skinned over, is advisable, with the avoidance of all imporous dressings that stifle discharge. This, early in the autolytic outbreak, will prevent or abort the eruption.

The patient ought to be confined to bed, with six-inch bed-blocks under the foot of the bed to hasten the return circulation. The leg congestion being gravitational, this elevation will quickly help to control itching and heat and tightness of the skin, and will go a long way to expedite healing, shortening the time taken measurably.

Treatment of the local patch is best done by applying boric fomentations or wet compresses of hypertonic saline solution, replaced every four hours for three days, to be followed by acriflavine emulsion soaks on gauze, renewed twice daily, for a further ten days. In the case of an open ulcer, the cleansing foment is, after the first three days, followed by carefully adjusted "red lotion" moist dressings morning and night; later, iodine-and-starch paste is applied as a thick spread, changed once a day, then, with improvement, once in two or more days. Bandaging should be firm and supporting, extending from the toes to below the knee, to counter the passive venous congestion of the leg, which only delays repair. This paste, with a tight bandage in the daytime and bed-blocks at night, is far and away better than the Unna-paste-impregnated bandage, which only holds up and confines any discharge, to become potentially, sometimes actually, harmful.

With the conversion of the hot dry surface of the primary patch into a moist freely discharging area, the patient is relieved of much discomfort; and the autolytic eczema begins to fade spontaneously, having itself needed little actual attention beyond the direct application of zinc cream morning and night, or the painting on of a weak ichthyol-in-calamine liniment (ʒi to ℥viii), as being protective and antipruritic. As covering for the arms cotton sleeves are cool and more acceptable to the patient than lint and bandages. When the scaling stage is reached, which is the end-process, a simple cold cream at nights is all that is required, any dressings being discarded

With the appearance of autolytic eczema, to secure relief for the itching, with peace of mind and enough sleep, nothing is so effective as fractional doses of phenobarbitone with bromide at spaced intervals for as long as is necessary. Autohaemotherapy is of some service at the start, so is non-specific protein therapy, though neither need be overdone or its value overestimated.

The diet should be lacto-vegetarian and salt-free, with an ample daily allowance of fluids (five or six pints, all told); condiments and spices are to be forbidden and over-flushing of the skin avoided. Two drugs are of real use, if indicated: acid. hydrochlor. dil. *B.P.*, given in full dosage soon after meals; and a one-drachm morning dose of magnesium sulphate in hot water, for a time, daily.

Summary

Autolytic eczema is not uncommonly met with in medical practice: the malady has increased in incidence during the war years. Much standing at work while suffering from a patch of open dermatitis in the leg is a predisposing cause, if an indirect one; thus far can autolytic eczema be accounted "occupational." The condition could not exist without the stubborn primary focus to begin it, and refuses to fade before this itself has healed. As a rule, the primary disease persists for long before the secondary outbreak appears; there is a wide, though varying and indeterminate, interval between the starting-point of the one and the other. Peculiarly, the trouble most often originates in a patch about the lower half of the leg or about the ankle; but not always; the primary mischief may occur in a localized dermatitis in the arm or elsewhere following injury. The typical expansive eczema autolytica follows a primary source in the leg; a milder, less extensive eruption when the local source is elsewhere. It is the rule that the eruption breaks out unexpectedly. What actually times and detonates the outbreak has yet to be determined.

The secondary eczema does not behave like a septic toxaemia, to show massive invasion by way of venous or lymph channels: the course taken, and the ready control by early treatment before secondary characters add themselves to the vesicular eruption, suggest a non-virulent auto-intoxication with sensitization. Sepsis alone does not afford so satisfying an explanation as does the theory of causation by autotoxic dermolysin, the constitution of which is not made manifest by present-day test methods.

It is not to be forgotten that "the skin faces both ways," having an internal surface coextensive with the external and of more importance to the bodily economy. Clearly, the mode of conveyance is vascular, the lysin reaching and acting upon the skin itself from within by way of the capillary loops of the papillary body, likely enough erupting at points of slowing in the circulation there subject to the play of physical influences.

The condition is well and truly named "eczema," qualified by the descriptive term "autolytic." Knowledge of the whole subject is fragmentary still; yet we know that all true eczema is in its proper form vesicular and reactional: that the correct treatment should not be symptomatic merely, but, to be radical enough, ought in the absence of a specific cure to aim at removing the cause. If the remedy is suspended or is unsuitable the disease may take a firmer hold, to become aggravated and in its course lengthy and perverse.

SEGMENTAL MOVEMENT OF THE PUPIL

BY

IAN S. McGREGOR, M.D.Glas., F.R.C.S.Ed.

Ophthalmic Surgeon, Glasgow Royal Infirmary

In 1911 C. H. Sattler described a pathological movement of the pupil which he called "Wurmförmige Contractionen der Sphincter Pupillae." It is a segmental movement, or twitch of the iris margin. It may be seen in a pupil which has no normal reaction to light, or in some cases in which the light response is present but much diminished. At any one moment during the examination of such a pupil only a single twitch may be apparent; or another similar twitch may appear at the same time further along the pupil margin. Loewenstein described some further cases in 1917 and 1919. He called the phenomenon "Harmonica Contractionen der Sphincter Pupillae." The worm contraction, or undulate contraction, of the pupil border is much less commonly seen than a single segmental movement or double synchronous segmental movement of the pupil in the field examined. The synchronous twitch giving the concertina-like movement would seem to be due to feeble impulses arriving at the same time, while the undulate movement occurred when these feeble impulses arrived at contiguous parts of the pupil border at slightly different times. The amplitude of the movement varies in different cases. Sometimes it can be seen with the naked eye, as in the patient quoted below blinded by quinine. The monocular loupe (× 10) or the low power of the corneal microscope (F/55 mm.) suffices for the recognition of most cases. Only the large inactive pupils of blind or near-blind cases of luetic optic atrophy required the higher powers of the corneal microscope for the recognition of the tiny abnormal movements which were present. They were best seen in the beam reflected from the lens surface. We have been able to observe a progress in amplitude of this segmental movement in a man who had paralysis of the pupil as a result of head injury. At first the movement was tiny, gradually increasing in extent with recovery until there was an entire contraction of the pupil.

The phenomenon has not stimulated much curiosity. In order to determine whether or not the sign had any localizing value a series of cases were examined. Of three cases of luetic optic atrophy with no light projection and large inactive pupils, examined under high magnification, two showed segmental contraction of small amplitude and one an undulate or travelling contraction of the pupil border. Two cases of post-traumatic optic atrophy having no light projection in the affected eye showed segmental contractions. Patients with partial field loss after head injury and patients with partial field loss in glaucoma showed no segmental movement. One man with Leber's disease having a visual acuity of 3/60 Snellen, right and left, had a marked segmental movement. A middle-aged healthy man blinded by quinine showed active segmental movement from the outset of the observed period, which extended over two months. The movement gradually acquired greater amplitude, merging into a total pupillary response to light. Even when the total response to light was established the segmental quality was evident in relaxation until it finally disappeared. Two cases of retrobulbar neuritis had those abnormal movements, and in these the pupils were markedly dilated. In the following cases the motor side of the pupillary arc was presumably affected. A middle-aged man sustained a basal fracture of the skull in falling off a bus. He had good vision in both eyes, but had a complete third-nerve palsy on one side, and was Wassermann-negative. There was an undulate movement of the pupil border. A similar case observed over some months gradually recovered and the segmental movement merged into the normal total response. An elderly woman, having good vision in both eyes and Wassermann-negative, developed an internal ophthalmoplegia of vascular origin, and in a pupil which was immobile directly and consensually to light segmental movement was seen. A young married woman —Wassermann-positive, myopic-astigmatic, with good corrected distance vision—complained that she could not read. Both pupils were dilated and responded poorly to light, and there was bilateral paresis of accommodation. Both segmental and undulate contraction of the pupil were seen, and occasionally there was a feeble total movement of the pupils. This woman has been observed over 18 months and the signs are unchanged; there has been no recovery with establishment of the normal contraction. Her antisyphilitic treatment has been erratic. Two cases of unilateral Adie's pupil showed the abnormal movement. Squinting amblyopes never showed the abnormality.

To watch the behaviour of the pupil in this respect under the influence of factors acting peripherally, routine mydriasis with homatropine 1% was studied. After about 10 minutes the lessening total contraction gave place to segmental contraction before immobility. On the other hand, no abnormal movement was seen after mydriasis from subconjunctival injection of cocaine 2% with adrenaline.

Discussion

This pupillary unrest may occur, then, in sufficiently severe disorder of the afferent or efferent nervous paths to the sphincter of the pupil. Further, it may be induced by the peripheral action of mydriatics which inhibit the choline flux, but not by those mydriatics which stimulate the sympathetic. It is not seen in the contracted pupil. It would seem to be due, first, to diminished conduction in the nerve paths to the sphincter pupillae, for the movement is seen only in pupils of diminished response; and, secondly, there must be a pathological variation or inequality of flux within the nerve plexus. Some vestigial impulses get through and produce a local twitch, and in the immediate neighbourhood these impulses fail, or arrive after an interval to produce an undulate reaction. The chronaxie of the nerve paths to the sphincter is unequal throughout its distribution in these cases. Wolfrum (1926), when examining the minute histology of the pupil, was struck by the radial distribution of the nerve fibres entering the sphincter pupillae, and he speaks of the Sattler phenomenon. If the distribution of the third nerve to the sphincter of the pupil were a fine uniform plexus it would be difficult to understand a local emergence of movement, but as it is supplied by twigs running into the muscle fibres and at right angles to them the explanation of the origin of the movement becomes acceptable.

Finally, the sign, so far as this short investigation will allow us to conclude, would not appear to have any localizing value; it is a fibrillation of the pupil resulting from impaired integrity of the nervous arc of the sphincter pupillae occurring at any part of the arc.

A. M. Harvey and F. T. Billings (*Amer. Heart J.*, 1945, **29**, 205) report three cases of coronary occlusion after the institution of therapeutic hyperpyrexia for sulphonamide-resistant gonococcal urethritis. All the patients were young adults with no previous cardiovascular disease. In no instance was the patient critically ill. Electrocardiograms in each case showed progressive changes similar to those observed in patients with occlusion of the anterior ascending branch of the left coronary artery.

Medical Memoranda

Fistula between the Small Intestine and One Horn of a Uterus Bicornis

The following notes of an unusual case of fistula may be found of interest.

CASE HISTORY

A single woman of low-grade mentality, 28 years of age, was first seen in March, 1944, at the obstetrical department, where she was found to be pregnant. The pregnancy was complicated by hydramnios and confirmed by radiography. On May 29 she was prematurely delivered of a stillborn exomphalic male foetus. The puerperium was characterized by an irregular temperature with rather offensive lochia, but she soon settled down and was discharged on the 14th day.

On July 6 she was readmitted complaining of an offensive vaginal discharge and severe perivulval irritation. The vulva was grossly excoriated and profuse discharge was coming from the vagina. On vaginal examination, among other debris several undigested cooked green peas were seen coming through the cervix uteri. The patient had eaten peas four hours earlier. The discharge continued while she was under observation, and consisted of undigested food giving bile-pigment reactions. It was obvious that a fistula existed between a high part of the intestinal tract and the uterus.

On July 26 the abdomen was explored and on the left side of the pelvis a curious pyriform uterus was seen. At the fundus there was an adherent matted mass of small-intestine coils. The coils were gradually separated, and one was found welded on to the fundus. On separation this coil had an opening the size of a sixpence continuous with the uterine lumen. Both openings were closed.

Further examination of the uterus revealed the fact that the pyriform uterine swelling was an enlarged horn of a uterus bicornis. Separate Fallopian tubes opened into the apex of each horn. It is probable that the fistula had resulted from an attempt to end the pregnancy.

I am indebted to my colleague Mr. Barnie-Adshead for the opportunity to operate on this case, and to Dr. J. C. Miller for help with the case notes.

Melaena due to Peptic Ulceration of a Meckel's Diverticulum

The case recorded below seems of sufficient interest and rarity to merit description. The occurrence of peptic ulceration in a Meckel's diverticulum is rare in any country, but seems particularly rare in England. In a review of the literature up to 1934 (Johnston and Renner, 1934) 60 cases of the condition had been described, of which only seven had come from English journals.

Meckel's diverticulum, a remnant of the vitelline duct, is present in 2% of the population, and is one of the sites of heterotopic gastric mucosa formation. It is prone to the same diseases—of which peptic ulceration with haemorrhage is one —as the stomach and the first part of the duodenum. The majority of cases occur in children and young adults of the male sex, although two of the four cases reported by Chesterman (1935) occurred in the female. The presenting symptom is rectal haemorrhage. The bleeding is often recurrent and may produce a severe degree of anaemia. Pain is not always present, but when it occurs is colicky in type and umbilical in situation. In the absence of perforation there is usually no clinical abnormality detectable on abdominal or rectal examination. It is impossible to demonstrate the diverticulum on radiological examination.

CASE REPORT

A boy aged 16 was admitted on June 24, 1944, with abdominal pain and the passage of blood per rectum for the previous 13 hours. The onset was sudden, and occurred while he was at work as a railway porter. The pain was colicky, and was situated in the region of the umbilicus; the attacks of colic lasted a few minutes and recurred every few minutes. The passage of blood coincided with the onset of the colic. While in the ward he passed several ounces of dark-red blood. There was no vomiting. He gave a history of three previous vague attacks of "stomach-ache" associated with constipation during the past year. Each attack lasted about one week. He had no previous melaena.

On examination the tongue was furred. The abdomen showed slight generalized tenderness and rigidity, but no mass could be felt. Rectal examination revealed the presence of blood, without any other abnormality. A pre-operative diagnosis of intussusception was made, and operation was proceeded with immediately.

Operation.—A right mid-abdominal split-rectus incision was made under open ether anaesthesia. There was no evidence of intussusception. The whole of the large bowel and some coils of the small bowel were distended with blood. On further search a Meckel's diverticulum was found on the antimesenteric border of the small bowel, 2¼ ft. from the ileo-caecal valve. The diverticulum and the whole of the bowel distal to it were full of blood, while the proximal bowel was collapsed and normal in colour. The diverticulum itself did not show any external evidence of inflammation, but there was a well-defined indurated area near the base. The diverticulum was excised and the bowel repaired transversely. The abdomen was closed without drainage.

He made an uneventful recovery, and was discharged 20 days after operation.

Examination of Specimen.—On section the absence of generalized inflammation was confirmed. Near the base was an indurated area half an inch in diameter, in the middle of which was a shallow ulcer a quarter of an inch in diameter, involving the mucosa only. In the centre of the ulcer was the open lumen of a small blood vessel from which blood could be expressed. Microscopical sections taken through the middle of the ulcer showed the presence of gastric mucosa with oxyntic cells.

I wish to thank Dr. H. H. MacWilliam, medical superintendent of Walton Hospital, for permission to publish this case; and to Dr. R. Y. Dawbarn for the preparation and examination of the microscopical sections.

Large Foreign Body in Stomach, with Complete Absence of Usual Symptoms

The following case may be considered interesting enough to merit publication.

CASE HISTORY

The patient, an African woman aged 29, mother of four healthy children, was admitted from the out-patient department with a diagnosis of "abdominal tumour"; she was a well-developed and well-nourished woman of medium height, and weighed 8½ st. She gave a history of "a lump in the belly," which had been present for about five years, was getting larger, and now interfered with her when weeding, as she found it difficult to stoop. She had no pain, vomiting, or other disturbance, and there were no signs of wasting or lack of nourishment.

On examination a large swelling was visible, extending from the left costal margin into the pelvis. It was smooth and firm to the touch, not tender, and was easily movable in any direction. This movement caused no discomfort of any kind. The patient had a very good appetite, and could eat a large meal of rice, fish, and vegetables without any discomfort. She was a very cheerful person, and looked upon her condition as a joke.

Owing to the size of the tumour I was forced to make a rather large incision in the stomach. The cardiac end was delivered without trouble, but the pyloric end was firmly gripped, and I had some little difficulty in releasing it. The mass when removed was a complete cast of the stomach with prolongations into the oesophagus and the duodenum. It was very firm in consistence, it could be dented with the finger, but the finger could not be forced into the mass. On section it had the usual appearance of a "hair-ball," consisting of fibres, mainly mango, rice grains, and other food debris. The patient made an uneventful recovery.

A Fibroma weighing 320 Grammes growing from the Posterior Vaginal Wall

Owing to the rarity of its nature, the following case may be of interest to others:

The patient—a married nullipara of 40—came up complaining of a blood-stained vaginal discharge for two months. She had very little control of micturition but was otherwise well. Her periods were regular and lasted 5 days in every 28. On examination a hard mass 3 in. in diameter was felt completely filling the vagina. It was dark red in colour but not friable, and was thought to be a cervical fibroma.

At operation, performed by Mr. Clifford White on Oct. 28, 1944, it was possible to pass a finger above the tumour and a normal cervix could be felt. The tumour was then found to be arising from the posterior vaginal wall 2 in. below the cervix. A left-sided Schuchardt's incision was made, but, owing to the size of the tumour, removal had to be by the process of morcellement. When about one-third had been removed in this way the capsule was stripped and the remainder of the tumour shelled out. The bed was obliterated with catgut sutures and the vagina and perineum repaired. The tumour was hard and not very vascular. It weighed 320 grammes and was histologically a fibroma.

Secondary haemorrhage from the perineal incision occurred on the ninth day. The bleeding-point, which was in the region of the internal pudendal artery, was ligated; the wound was packed and sulphanilamide powder insufflated round the edges. Four pints of Group O (IV) blood were given. Recovery thereafter was good. The vagina healed well, and when seen three months after operation the patient's condition was quite satisfactory.

I am indebted to Mr. Clifford White for permission to publish the above details.

Reviews

BONE-GRAFTING FOR FRACTURES

Bone-Grafting in the Treatment of Fractures. By J. R. Armstrong, M.D., M.Ch., F.R.C.S. Foreword by R. Watson-Jones, M.Ch.Orth., F.R.C.S. (Pp. 175; illustrated. 25s.) Edinburgh: E. and S. Livingstone. 1945.

This may be regarded as a supplement to Mr. Watson-Jones's book on fractures. The amount of work the author has put into it, considering his Service commitments, is truly commendable, even allowing for the aid of his enterprising publishers. As it seems likely that this is but the first edition of a work which will rapidly be added to, we venture to make some suggestions.

The descriptive operative surgery of the past has often been rendered valueless by the lack of analytical assessment. When Mr. Armstrong is in a position to quote statistics upon results his work will be more valuable. The justifiable enthusiasm for the onlay graft (and he was less enthusiastic only two years ago—see *Lancet*, Aug. 14, 1943) should be tempered by acknowledgment of the pioneer work of M. S. Henderson and of Willis C. Campbell. The latter has admirably described and illustrated the technique, to which little has been added since. The meaning of the term "creeping substitution," applied to the replacement of dead graft by living bone, may be well enough known, but it would be worth while drawing attention to Phemister's contribution to the subject. The question of the osteogenetic properties of the tibia is badly stated and should be clarified. In spine grafting the idea of roughening the neural arches with a chisel or file would be scorned by those surgeons who count their spine grafts in hundreds. Mr. Armstrong should realize that the operative treatment of adduction fractures of the femoral neck did not start with Smith-Petersen, whose nail, after all, is merely a mechanical derivative of the fibular graft previously in common use in Holland. Our own Hey Groves contributed something to that problem at least 30 years ago.

It is interesting to see how Mr. Armstrong differs from his sponsor (*Fractures and Joint Injuries*, 3rd edition) in some important respects. For the Monteggia fracture the former does not hesitate to excise the head of the radius at the same time as the ulna is grafted; the latter condemns the procedure. Neither gives us statistics to indicate which is right. Armstrong uses an Esmarch's tourniquet; Watson-Jones does not like it. The former is even prepared to leave a tourniquet on the leg for two or three hours, and not remove it until plaster has been applied. This is bad. The liability to ischaemic lesions of nerves, the reduced vitality of exsanguinated tissues, reactive hyperaemia, and the constrictive effects of plaster, form a serious combination of danger factors. Mr. Armstrong, no doubt, is a gifted technician, and even if his results are impeccable his teaching should be safe for the not-so-gifted. It is all very well for Watson-Jones to write in his foreword hyperbolically about the infection of a closed fracture being a "disaster worthy of a court of inquiry." Devitalization of tissues is well known to be an excellent breeding-ground for infection, and a book which condones it should equally be criticized.

We do not think that Mr. Armstrong has altogether been helped by Mr. Hennell's coloured photographs, in which so often a very dark blue background obscures the detail of the instruments being used. The lavish scale upon which this book has been produced should be noted at a time of paper scarcity. If printed in uniformity with its bigger companion by Mr. Watson-Jones, and if blank spaces were filled, it could have occupied a quarter less paper. One has a feeling that it is premature and has added little of real value at a time when the practice of bone-grafting is still in a state of flux.

RADIOLOGY IN 1944

The 1944 Year Book of Radiology. Diagnosis, edited by Charles A. Waters, M.D.; Associate Editor: Whitmer B. Firor, M.D. Therapeutics, edited by Ira I. Kaplan, B.Sc., M.D. (Pp. 448; illustrated. 31s.) Chicago: The Year Book Publishers; London: H. K. Lewis and Co.

In spite of five years of war the *1944 Year Book of Radiology* well maintains the high standard of former years. Because of the restrictions of the war the papers reviewed come, in the main, from North and South America and the British Empire.

The diagnostic section, occupying some 232 pages—rather more than half the book—contains many references of great interest. In the skeletal section are accounts of x-ray appearances in yaws and leprosy and a description of a case of the Morgagni-Stewart-Morel syndrome (hyperostosis of the calvarium associated with endocrine and mental disturbances). In the chest section L. L. Robins's paper on fifteen cases of bronchiogenic cysts is summarized, and also Kerley's work on the aetiology of erythema nodosum and the x-ray signs in the chest. Notes are included on the pulmonary changes in strongyloidiasis, tularaemia, and coccidioidomycosis.

Articles of interest on the heart are those on calcification of the valves and pericardium, angiocardiography in patent ductus and rheumatic carditis, the technique of angiocardiography, and on the x-ray signs of patent ductus. Clayton and Schatzki's account of the changes in the gastro-intestinal tract in sclerodermia of the oesophagus, small intestine, and colon is noted, and also a paper on the same subject by Lindsay, Templeton, and Rothman. There is an interesting description of Schatzki's technique for the small-intestine enema given through a duodenal tube, and in the obstetric section there is reported Chassar Moir's investigation into the soft-tissue shadows of the pregnant uterus, with special reference to placentography.

Again, the section on radiotherapy, without revealing any startling new developments, contains a comprehensive survey of the year's work in this field. The *1944 Year Book* is, as before, a most welcome compendium of radiological information.

EFFECTS OF CLIMATE ON MAN

Climate Makes the Man. By Clarence A. Mills, M.D., Ph.D. (Pp. 186. 7s. 6d.) London: Victor Gollancz. 1944.

This chatty little book is written in a style unlikely to appeal to the medical reader. The first person singular is mentioned with an unfashionable frequency; experimental animals are given Christian names such as Ivan and Hilda; the dog is called "man's closest companion"; and man himself when not "I" is "homo sapiens." There is an arch facetiousness about the book, as when the author finds it necessary to assure the reader that a scientific colleague's interest in brothels was "purely platonic." As it is difficult to believe that the mind of a professor of experimental medicine really works at this level, we must assume that the book is a bad example of "writing down to" the lay public and that the more intelligent section of the laity will feel appropriately affronted.

This is a pity, because the book contains a lot of most interesting information not readily available elsewhere about the effects of climate on the life and health of men. Such diverse subjects are mentioned as the effects of climate on vitamin needs, longevity, the onset of puberty, psychological reactions, the incidence of disease, the outbreak of war, and the pageant of history. The information given is accurate, though often so superficial that the reader longs for a reference list.

Perhaps Prof. Mills will now write a bigger book on the same subject for doctors or for the intelligent laity.

THE HAIR AND SCALP

The Hair and Scalp. A Clinical Study. (With a Chapter on Hirsuties.) By Agnes Savill, M.D., F.R.C.P.I. Third edition. (Pp. 304; illustrated. 16s.) London: Edward Arnold.

Not the least of Dr. Savill's achievements has been her success in getting a new edition of this excellent work published in the sixth year of the greatest war known to history. The story of her struggles forms one subject of the interesting preface to the new volume. The strong point of this book remains the account of the physical properties of the human hair and their relations to the problems of cosmetics and the minor capillary disorders which form so large a subject of exploitation to the hairdresser and beauty specialist and in which the ordinary medical man is commonly so ill informed when called upon for advice by anxious patients. He need not remain so if he takes the trouble to read and digest Dr. Savill's discussion of these problems. She has again had the advantage of Dr. Astbury's help. He contributes the chapter on the molecular structure and elastic properties of hair, and in this edition has had to modify his views in some matters, notably in his discussion of the methods of permanent-wave production. It will probably be news to many that permanent waving can now be achieved at a comparatively low temperature. This discovery we owe to Prof. Speakman of the Department of Textile Industries, Leeds University. It depends on the use of chemicals, first to relax the hair to make it take the shape of the curler more easily and then to harden it again and fix it in the curled condition. It seems that this method of permanent waving, though it cannot be said that it does no harm to the hair, is less dangerous than the other methods, which need exposure of the hair to very high temperatures over some two and a half hours. This British discovery has been widely exploited and is very popular in America, but in this country its development has been hampered by the necessity for concentration on war effort, and it is still far from being generally known on our side of the Atlantic, though practised by some London trichological artists.

Another very interesting section of this book is the chapter on hirsuties, one of the most serious cosmetic disasters to which the female sex is exposed. Dr. Savill has now been the leading woman dermatologist in this country for a good many years and has probably had more experience in treating this condition than any of her male colleagues. She has embodied the results in this chapter, which should be studied carefully. Every dermatologist knows that hirsuties is a difficult condition to treat, but many will feel after reading Dr. Savill's discussion that it is far more amenable than they have been accustomed to consider it. We once more commend this work to all who are concerned in the care of the hair and scalp, whether they are members of the medical profession or not.

The *Dentists Register* for 1945 has now been published for the Dental Board of the United Kingdom by Constable and Co., Orange Street, Leicester Square, W.C.2, price 15s. The total number of names appearing at the end of last year was 15,438, being 34 more than the figure for 1943. All but two of the new entries were of persons registered as graduates or licentiates.

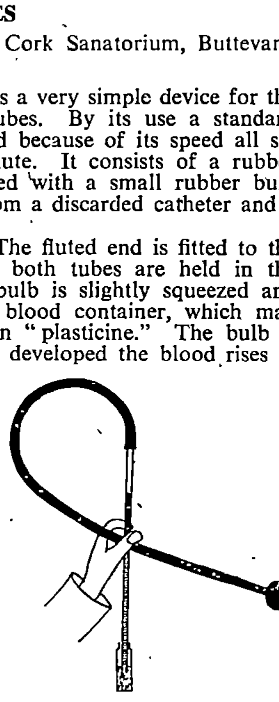
Preparations and Appliances

DEVICE FOR FILLING BLOOD SEDIMENTATION TUBES

Dr. M. M. CONRAN writes from Cork Sanatorium, Buttevant, Co. Cork:

The accompanying sketch shows a very simple device for the filling of blood sedimentation tubes. By its use a standard technique can be maintained, and because of its speed all six tubes can be filled within a minute. It consists of a rubber tube, fluted at one end and fitted with a small rubber bulb at the other. It can be made from a discarded catheter and a medicine dropper.

The procedure is as follows: The fluted end is fitted to the top of the glass tube and then both tubes are held in the middle by the left hand. The bulb is slightly squeezed and the glass tube inserted into the blood container, which may be steadied by an assistant or in "plasticine." The bulb is then released and by the suction developed the blood rises in the tube. By alternately squeezing and releasing the bulb five times standard mixing of the citrated blood is obtained. The blood is then brought up slightly above the 200-mm. mark, and the rubber tube squeezed against the glass one by the left thumb. The final adjustment is made by rolling the glass tube on the rubber one with the left forefinger, which causes a slight rise or fall of the blood, depending on the direction of the roll. Keeping the finger and thumb steady the tube is placed in the rack and pressed firmly down while the tubber tube is removed by a steady pull with the right hand.



With a little practice speed and accuracy are soon attained. I have found that the time taken to set six tubes is far shorter when using this method. I hope also that this simple device may be useful to those interested in avoiding the periodic mouthful of blood which is the distasteful experience of many.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MAY 5 1945

UNDERFED CHILDREN

At the end of the war of 1914–18 the majority of scientists on the Continent attached most importance to calories, while the interest of British workers was focused on the recently discovered accessory food factors. The British team in Vienna made their classical investigation on rickets and found cases of scurvy; but it was felt that, besides the widespread rickets and occasional scurvy, many more evidences of vitamin deficiency might have been found. Apart from the celebrated study on keratomalacia in Denmark we have little satisfactory information about the frequency of vitamin A deficiency. Scurvy and, still more, beriberi and pellagra were diseases of soldiers rather than of civilians, whose diet was made up of high-extraction flour and vegetables. But the studies made during the siege of Madrid have shown that under even worse conditions the specific deficiency diseases attack only those who are particularly susceptible. The majority suffer from general malnutrition or from secondary diseases, particularly tuberculosis. And in Madrid the specific deficiency diseases—pellagra, optic neuritis, paraesthesiae, and famine oedema—were rare among children under the age of 15.[1] It is probable that, rickets apart, the great majority of children in Central and Eastern Europe showed no definite signs of any specific deficiency disease, and suffered from general malnutrition or from secondary diseases, particularly tuberculosis. We have records of this general malnutrition as detected by clinical examination and by the pelidisi system. This particular system of treating anthropometric data has been criticized; but it has the merit that it gives measurements in figures, free from personal bias, of some deviation from normal, and this is reduced as the nutrition improves. These data could be used for comparison of the state of children to-day with that of children in 1919–21. The tuberculosis death rates in age groups 1–4 and 5–14 in Germany and in age groups 6–10 and 11–15 years in Vienna in 1920 were twice as high as in 1914.

It is impossible to form a correct estimate of the food supply in occupied countries before or after liberation. We know the rations: in most countries they covered over 90% of the possible foodstuffs, and were wholly insufficient to maintain even a moderate degree of health during the years of occupation. In country districts it has not been possible to enforce food control; in towns rations have been supplemented from all sorts of sources, ranging from the genuine black market to the workman who rides a bicycle into the country to buy food and sells some and keeps the rest for his family. A little is added to the legal price at every stage of these transactions. Those who could not themselves buy in the country or afford high prices have found it difficult even to get food to supply sufficient calories. In any case fats and animal protein have been scarce because imports of vegetable oils have been cut off, livestock have been killed off, cattle are lean, and milk yields poor. The increase in the knowledge of food requirements has, however, reduced the risk of deficiency diseases. It is said that owing to the wide use of vitamin D rickets became less common in Belgium than before the war. Special allowances have been made for children. Whole milk has been reserved for them, usually up to the age of 14 (but in Belgium and Holland the fat content has been reduced to 2.5%). The younger children have, on paper at all events, fared comparatively well; it is only above the age of 8 that the requirements according to the League of Nations standard have not been covered by the rations. In France and Belgium adolescents have had little more than half their requirements unless their food was increased from some irregular source.

Before D day there was evidence in the industrial districts of general malnutrition, in the failure, particularly of the older children, to put on weight, and a rise in the tuberculosis death rate. With the invasion traffic has been disorganized: it has become more difficult to transport food to the towns, and the distribution has become more unequal. The import of food to Paris was at its lowest in August of last year. Convoys were rushed in within a week of liberation, but with 4,000 bridges destroyed, four-fifths of the locomotives gone or out of order, and half the transport capacity taken up by the military, it has been impossible to keep up an adequate supply of food to the towns. Even now, with 1,250 bridges repaired and 10,000 lorries supplied, Parisians have still to depend on forays into the country to get food enough to live on; meat rations are irregular; milk arrives sour owing to the slowness of the trains; and only the youngest children can get a wholesome supply. There is more malnutrition now than before liberation. Conditions in Holland, Norway, Greece, and Yugoslavia are far worse than in France. Even if food could be distributed evenly there would still be a serious shortage. While fighting continues both in Europe and in the East it is difficult to spare the ships to bring over food from the great producing countries overseas. The easiest way to supply Europe would be to draw on stocks that have accumulated in Britain. When malnutrition was debated in the House of Commons on March 28 and 29 it was stated that the Minister of Food had sent, or agreed to release, to the liberated regions, which include some Mediterranean areas, 900,000 tons of food from our stock of 6 million tons. When we recall that in 1917, at the height of the U-boat campaign, our stocks were reduced to 1 million tons of grain and sugar for four days[2] we may well feel that we could now safely spare considerably more to meet this emergency. With the destruction of farms, the lack of fertilizers and implements, the interruption of spring sowing, and the flooding of large areas in Holland, this year's harvest will certainly be scanty. Further relief will be needed during 1945–6 to provide sufficient calories. Animal products will be short for several years, and supplies can be obtained only by keeping down consumption in the more fortunate countries..

---

[1] Grande-Covian, F., and Jimenez-Garcia, F., *Rev. clin. Esp.*, 1940, **1**, 323.

[2] Beveridge, W., *British Food Control*, Oxford University Press, 1928, pp. 91, 124.

According to a recent report in the *Journal*[3] Dutch children, aged 7 to 15 years, brought over to England in February had been living for a long time mainly on bread, potatoes, and cabbage. They did not appear seriously wasted, but were generally undersized; they must have been much under weight for their size, as they gained up to 6 lb. 6 oz. in three weeks after arrival. Feeding these children presented no serious difficulty; the only precaution taken was to limit the amount of fat and the total calories during the first week. When the initial difficulties are over nutrition will improve on almost any diet that will provide calories. The typical dinners supplied to children in canteens run by relief organizations for malnourished children in 1919–21 provided daily an average of only 5 grammes of animal protein, the vitamins A and D of 70 ml. of milk, and almost no vitamin C. The children probably got some carotene and C from vegetables at home, but precious little animal protein; yet their condition improved steadily. Children from the areas of Holland where rations have fallen to 300 calories a day will be in a far worse condition. Experience among the International Brigade and Spaniards in concentration camps in Southern France showed that no state of starvation, except the final coma, is beyond hope.[4] In the Bengal famine the more severe cases were divided into (1) collapsed cases, likely to die without parenteral feeding; (2) the less collapsed cases, who were capable of recovery when fed by mouth; and (3) those capable of taking a simple milk diet.[5] For the first group intravenous injections of protein hydrolysates, containing glucose, riboflavin, niacine, and thiamin, were recommended. It was claimed that this treatment saved patients who otherwise would certainly have died. The second group needed to be fed with small amounts at short intervals; it might be necessary to feed by nasal tube. This group and the third group were given liquid mixtures supplying 800 to 1,200 calories per day; about half the calories were provided by sugar (4 oz.); the remainder were made up with flour or milk. Recent studies on the efficacy of various nutrients in maintaining life have shown the special importance of aneurine; it would therefore be advisable to give one international unit of aneurine for every gramme of sugar.

TREATMENT OF SEVERE STARVATION

In 1939 Elman and Weiner[6] reported the use of an acid hydrolysate of casein fortified by the addition of tryptophan and by supplementation with cystine or methionine for intravenous alimentation of human subjects; evidence was obtained of satisfactory utilization of the amino-acids, and favourable therapeutic effects were observed. The work of Elman and Weiner constituted a practical application of the observation of Henriques and Andersen[7] in 1913 that nitrogen equilibrium could be maintained in the goat when the sole source of nitrogen was provided by the intravenous administration of amino-acids. During the last few years numerous papers have appeared dealing with the clinical use of hydrolysates of protein for alimentation either by the intravenous or oral routes (for reviews see Gaunt[8] and Cuthbertson[9] and this *Journal*[10]); most of these referred to the use of the American product "amigen," a pancreatic hydrolysate of casein, and it has been stated by Allbright[11] that complete maintenance can be effected with "amigen" and glucose alone for as long as forty days. Some attention has also been paid to acid hydrolysates and to digests of meat prepared with papain. The ideal preparation is yet to be found; pancreatic digests are highly susceptible to bacterial contamination during their production and are therefore liable to be pyrogenic; papain digests, while relatively free from this disadvantage, may contain partial breakdown products of protein which are harmful, and the acid hydrolysates require fortification with tryptophan, which is not a very easily accessible substance. The only report so far published on the use of protein hydrolysates in the treatment of starvation has come from India (Narayanan and Krishnan[12] and Krishnan, Narayanan, and Sankaran[13]); a considerable measure of success was claimed as the result of intravenous administration of papain digests of meat together with glucose to patients who were so far weakened by starvation that they were unable to take anything by mouth. The Indian work was undertaken in conditions of such difficulty that a carefully controlled investigation was not possible, and the evidence for the favourable effect of intravenous alimentation rests on clinical observation only.

The food situation in the Netherlands is exceedingly grave. This applies particularly to the large towns of North-West Holland, where there is good reason to believe that few people have been getting more than 800 calories and where they may now be getting only about 400 calories daily. After considering the data available the Netherlands authorities and the military authorities concerned agreed that the food situation in N.W. Holland was so serious that special measures would be required if a large proportion of the population were to be resuscitated; being impressed by the evidence in favour of the use of protein hydrolysates, they invited the Medical Research Council to advise on the provision of suitable preparations in adequate quantity. At the same time a scheme for the application of the emergency treatment was agreed upon with the Netherlands authorities; this scheme included not only the formation of relief teams but also full provision for clinical and laboratory study of the cases of extreme starvation, so that the best method of treatment might be determined without delay. As the result of work carried out during the last eighteen months the Medical Research Council was in a position to give the necessary technical advice, and in view of the urgency of the need the Ministry of Food and the Ministry of Supply took immediate steps to increase production; with the whole-hearted co-operation of the firms concerned the amount of material which was asked for was produced in less than the specified time. Since it also seemed desirable to test the efficacy of plasma and serum in the treatment of extreme starvation, large supplies of these materials were requested and were furnished by the Lister Institute. The work in Holland is now in progress. Representatives of the Medical Research Council and of the Ministry of Food, together with American experts, are acting, at the invitation of the Netherlands Government, as scientific advisers.

It is now depressingly apparent that the problem of treatment for extreme starvation is of wide extent; it concerns a proportion of British prisoners of war and large numbers of occupants of enemy concentration and labour camps. Quite recently the Medical Research Council, at the request of the military authorities, has nominated a further team of three experts to proceed to the Continent to study the value of protein hydrolysates in treatment of starvation; this team is already at work with full equipment for the investigation required. Provision has also been made, at the request of the Ministry of Health, for material to be available for repatriated prisoners of war who may reach E.M.S. hospitals in urgent need of treatment. All these demands have increased the need for medical personnel, and use has been made of Belgian and English medical students who were enrolled, trained, and organized in anticipation of such a need. Two methods of treatment were considered. In the first a solution of protein hydrolysate, which may be prepared by complete enzymic digestion ("amigen") or by acid hydrolysis and subsequent fortification with tryptophan, is given by intravenous infusion. The second method consists in administration of the hydrolysate by slow intragastric drip, and in this case the material is an enzymic digest of casein or meat in which the digestion has not been carried so far. In both cases glucose is given in large amount to provide energy and thus to spare the amino-acids for purposes of repair. Vitamins are also given to enable the glucose to be utilized and to prevent the development of acute deficiency states. It is anticipated that successful treatment should lead within three days to resuscitation to the point at which ordinary food may be taken.

It is impossible at the present stage to predict the ultimate value of the protein hydrolysate treatment in extreme starvation, although there is already evidence that the intractable diarrhoea which is a prominent feature of the condition responds well to the intravenous method. It is much to be hoped that the intragastric drip will prove to be a satisfactory alternative form of administration; if so it will become the method of choice, not only because suitable material is so much more easily accessible but also because its use will be free from the risks which, at present at least, seem inseparable from the intravenous administration of hydrolysed proteins. Apart altogether from the prospect that the availability of protein hydrolysates may provide a valuable therapeutic measure in the present medical emergency, the studies which will be carried out offer the promise of useful information for the future; the observations which are made may be expected to have a bearing not only on the immediate problem but also on the treatment of all conditions of malnutrition associated with impaired absorption from the alimentary tract.

CONGENITAL DEFECTS AND RUBELLA

A curious association between maternal infection in pregnancy and congenital malformations in the infant seems to be a new manifestation of rubella. It is unlikely that such a dramatic sequence could have been overlooked in the past. In fact Gregg,[1] who first drew attention to it, traced examples back only until late 1939. Moreover, the defect which first attracted his attention was a congenital cataract which did not conform exactly to any of the clinical types previously encountered. This observation naturally aroused great interest. In a preliminary survey in South Australia Swan and his associates[2] examined 61 infants and found 36 with these congenital defects—cataract, deaf-mutism, heart disease, and mental retardation. The history of these 36 revealed that in 31 of the mothers there had been an illness during pregnancy (usually in the first three months) which was thought to be rubella. In 4 infants there was no maternal history of an exanthem. The mother of the remaining infant, who had a congenital corneal opacity, had had mumps during pregnancy. Viewed in another way, the survey showed that 49 mothers who suffered presumed rubella gave birth to 31 infants with congenital defects; 9 mothers who had had measles in pregnancy all produced normal infants; 1 of 2 mothers who had had mumps bore a child with a corneal opacity. Continuing their observations the same team later reported[3] 10 further examples of congenital defects in association with maternal rubella. Adding these to their 31 previous cases and to the 68 cases reported by Gregg, they find an impressive total of 109 such associations in Australia alone. Further examples have been recorded in America by Reese[4] (3 cases) and Erickson[5] (11 cases), and by Hope Simpson[6] (2 cases) in this country. The main points of agreement in the published data appear to be: (*a*) that the association is with rubella and not with other transmissible diseases (though not without exception); (*b*) that the risk of congenital defect is greatest if the rubella occurs in early pregnancy (i.e., within the first three months); and (*c*) that there are infants with congenital defects in which no link with a maternal transmissible disease can be traced.

Any explanation of the possible sequence of events is to some extent bound to be speculative. The general inference is that the unknown virus of rubella (with virulence possibly enhanced in the war years) is showing the preference of certain viruses for developing embryonic tissue. This it does by attacking the foetus via the placental circulation just at a time when important developmental changes are taking place in the foetal heart and eye. The high incidence of congenital heart disease suggests to these observers that the rubella virus has a primary affinity for vascular tissue, the lens damage being explained by possible indirect action through the hyaloid artery. Swan[7] later demonstrated in 3 infants who died of their defects a disproportionate vascular damage in the kidneys, the principal lesion being a glomerular sclerosis. While this view of pathogenesis is supported by recorded examples of intra-uterine transmission of other virus infections,[8] certain questions remain unanswered. Is the association between presumed rubella and congenital defects a significant one, or does it arise from pure chance? Swan and his associates[9] admit that a survey of the kind they undertook is likely to attract reports of the positive event; hence their material must necessarily be selective, perhaps highly so. Secondly, was the maternal disease rubella? Gregg was doubtful about this, but the other workers appear satisfied that it was so in most instances. In some cases the diagnosis was in retrospect unsatisfactory, and in others hardly justifiable. We cannot exclude the possibility of a chance association between congenital defects and true maternal rubella. A systematic investigation of rubella in pregnant women is called for.

CARBACHOL AND ITS ANTIDOTE

Recently two deaths have been recorded resulting from an overdose of carbachol. This is the pharmacopoeial name for the carbaminoyl ester of choline, which is sold in this country under the proprietary name of "moryl." Carbachol is used for these purposes: it is used by injection in a dose of 0.25 mg. for retention of urine or intestinal stasis, it is given as eye-drops to lower intra-ocular pressure, and it is also applied by electrophoresis in rheumatic infections. The first death occurred in an Oxford hospital due to a mistake by which the material intended for external application contained in an ampoule was injected under the skin, with the result that the patient received 400 times the dose intended. The second has now occurred due to precisely a similar mistake. In the comments which have been made concerning these fatal accidents no one has so far called attention to the fact that a completely effective antidote to carbachol is generally available. Carbachol acts in the same way as, though for a longer time than, the substance acetylcholine, which is known to be liberated in the body at the vagal nerve-endings. In excessive dose it causes violent intestinal contraction, vasodilatation, severe cardiac slowing, and secretion of mucus in the bronchioles. All these effects are promptly inhibited by the injection of atropine sulphate in the ordinary dose. Many antidotes are suggested for poisons of one sort or another, and these antidotes are effective in varying degree. Some are found in practice to have very little action at all. So far as it can be assumed that the human being behaves like the dog or the cat, it is safe to say that atropine is a perfect antidote for an excessive dose of carbachol, and that if it were given very large doses of carbachol would be immediately neutralized.

THE HEART IN RHEUMATOID ARTHRITIS

How far rheumatism and rheumatoid arthritis may be regarded as manifestations of the same disease, having a common aetiology, has been much discussed for many years. There are certainly points of similarity in the cardiac lesions, and they appear to occur more frequently than coincidence would allow. The report by Dennison Young and John Schwedel[1] of post-mortem findings in 48 cases of rheumatoid arthritis is therefore of interest. In only 6 of these cases were the patients under the age of 45 at death, and, of these, 1 appears to have died of acute rheumatism. In 24 cases the lesions were thought to have some resemblance to those of acute rheumatic carditis. Except in 2 cases all these lesions were old and healed, which is not surprising, as many of the patients were old. In several the valves were calcified. In 10 cases there was pericarditis. The incidence of disease on the several valves was similar to that of acute rheumatism; but the description of the valvular lesions is hardly detailed enough, and the incidence of mitral stenosis is not given. Microscopical examination of the myocardium showed Aschoff bodies only once, in a young patient; but again this is not surprising, as the majority of the patients were old at death. Scarring in the myocardium was found in only 2 instances, which seems an unduly low incidence for acute rheumatism. In one instance acute pericarditis was present at the age of 75, and in several bodies there was an obliterated pericardial sac without valvular lesions, which is a curious observation. In rather a large proportion of cases clinical examination had given negative results, perhaps because the lesions did not give rise to conspicuous physical signs.

From a cardiological point of view these cases were not typical of rheumatism. There was little cardiac disability; but it must be noted that the patients were for the most part unable to get about. Although the age incidence is different, we may recall the rheumatoid arthritis of children (Still's disease), in which pericarditis is not uncommon but endocarditis is rare. Young and Schwedel are inclined to think that rheumatoid arthritis and acute rheumatism are fundamentally the same. The question will remain undecided until the aetiology of both is known. While there is much to support the view that they have a common cause, there are considerable differences in morbid anatomy, clinical course, and response to salicylates. Further studies of the cardiac lesions of rheumatoid arthritis will be of interest.

ADRENALINE AS AN ANALGESIC

Adrenaline has been used to reduce the pain of leprosy since the observations of Muir[1] in 1927 and of Wheatley[2] in the same year: they recommended the intramuscular injection of 0.25 mg. adrenaline—that is, 0.25 c.cm. of the pharmacopoeial solution—because of the striking relief it gave. In 1928 Muir and Chatterji[3] recommended ephedrine by mouth for the same purpose: 30 mg. ephedrine sulphate relieved pain in 15 to 30 minutes, and the effect lasted for 12 hours or longer. The most reasonable hypothesis to explain this action is that the pain is due to leakage of fluid from the capillaries at the site of the leprous reaction, leading to swelling and tension. Adrenaline would make the capillaries less permeable, arrest the leakage, and diminish the tension. Ephedrine would raise the concentration of the patient's own adrenaline by lessening its rate of destruction.

Ivy and his colleagues at the Northwestern University in Chicago[4] have recently investigated the statement that adrenaline has an analgesic action. There is the clinical evidence of its use in leprosy, and experimental evidence obtained by Kiessig and Orzechowski.[5] These authors observed a rise in the pain threshold after intravenous or subcutaneous injection of ephedrine and other sympathomimetic substances such as amphetamine and desoxyephedrine. Ivy and his co-workers injected 0.1 mg. adrenaline into the carotid arteries of dogs and into their veins. They measured the pain threshold by preparing the dogs with two metal fillings in the cuspid teeth, so that a current of measured voltage could be applied through the fillings. They determined the peak voltage necessary to produce the slightest reaction. After intravenous injection the threshold rose so that the dog's sense of pain was least after 45 minutes, and the diminished pain sense was still obvious after 2 hours. This diminished sensation was peculiar to pain, for the dogs' scratching and attempts to catch fleas continued after the adrenaline injection, when they were analgesic, as before. Similar observations were made on human subjects. The authors consider that there is a specific action of adrenaline on the pain-perceiving mechanism, and prefer this view to the possibility that the cortical stimulation, which the injection of so large a dose of adrenaline evokes during the next ten minutes, results in some reflex inhibition of the thalamic pain centres. They think the analgesic effect lasts too long to be explained thus.

A RAPID METHOD OF LOCATING SHELL FRAGMENTS, USING X RAYS

BY

T. N. P. WILTON, M.R.C.S.
T/Surg. Lieut., R.N.V.R.

The following method of locating foreign bodies (metallic), with the assistance of *x* rays, is thought worthy of description by reason of its extreme simplicity and the rapidity with which it enables shell fragments to be removed when deeply embedded in muscle.

The method was developed in the County Hospital, Dover, where from time to time numbers of badly wounded patients were admitted as a result of naval actions in the Channel and hostile cross-channel shelling. The majority of these patients were severely shocked and had large pieces of shell fragments in their limbs.

It is difficult and time-taking to find and remove these F.B.s, particularly in the thigh. This task was aggravated when the F.B. eventually came to rest, deep in the limb muscle, some 10 to 12 in. from the entrance wound. The method has also been of use in removing F.B.s in the forearm and vertebral muscles. When the F.B. is palpable under the skin no accurate location is of course required.

The problem is to correlate accurately and quickly the radiographic appearance with the limb as it lies on the operating table. If anatomical landmarks are available the problem is to some extent solved, but with this apparatus no landmarks are necessary.

The Apparatus

(1) Camel-hair brush.

(2) Solution of gentian violet in ether.

(3) Strip of adhesive tape 30 in. long, containing symmetrically spaced lead shot (gauge 6 from a twelve-bore cartridge). This is made by placing a piece of tape, 1 in. wide by 30 in. long, on a table with the sticky side up. The shot is placed firmly on the sticky surface at intervals of 1 in. (See Fig. 1.) Cardinal points are marked by three pellets—i.e., at every 12 in. The pellets are enclosed by a second strip of adhesive tape placed over the first, adhesive sides together. (See Fig. 2.)

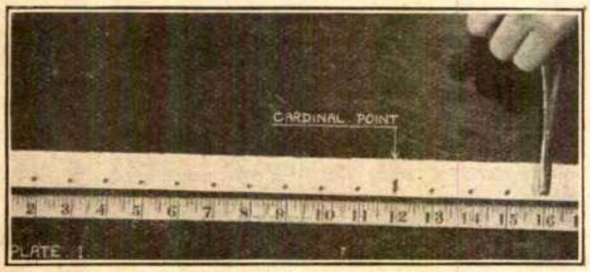

FIG. 1

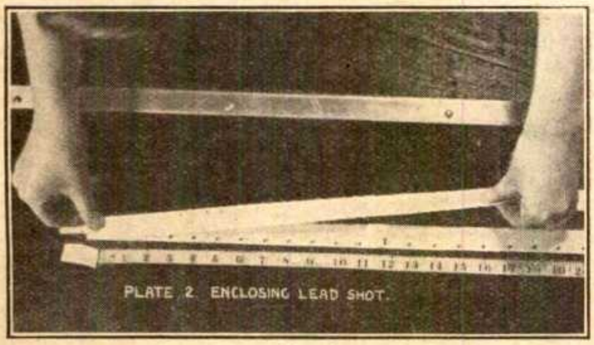

FIG. 2

Technique

The injured limb is stripped of clothing preparatory to examination and radiography. The tape is laid along the length of the limb and the gentian violet solution is applied in small dots to correspond with the lead shot in the tape, particular attention being paid to the cardinal points. (See Fig. 3.) A cardinal point is laid in the same transverse plane as the entrance wound where possible. The ether evaporates rapidly, leaving the aniline dye strikingly marking the skin. (See Fig. 4.) The whole technique takes but a few seconds, and every patient with a suspected F.B. can be marked as a routine. Thus at operation the gentian violet dots on the limb correspond to the opaque lead shot on the *x*-ray film. The transverse plane of the F.B. is at once evident. A lateral skiagram of the limb will show whether the F.B. lies anterior or posterior to or level with, say, the femur. The technique is not used on the lateral views as this is unnecessary and raises difficulties in the shot-F.B.-film distances to overcome distortion.

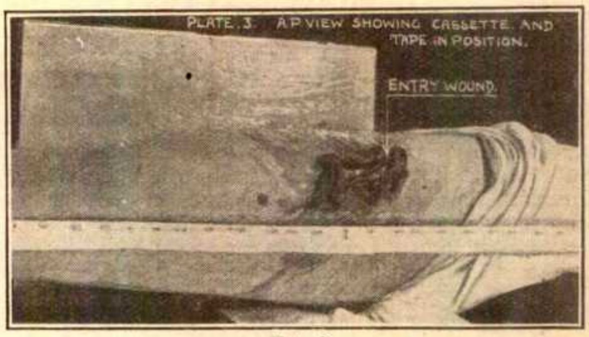

FIG. 3

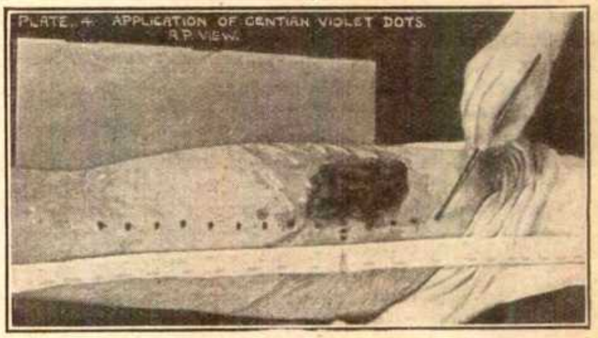

FIG. 4

In no way is this method intended to compete with the more elaborate methods of F.B. location, which no doubt are of first-class use in more leisurely circumstances.

I am indebted to the Medical Director-General, Royal Navy, and to Mr. A. R. Jordan, F.R.C.S., medical superintendent of the hospital, for permission to publish. Acknowledgment is made to Mr. J. Sutherland, M.S.R., for his enthusiastic co-operation.

IMPERIAL CANCER RESEARCH FUND

The annual general meeting of the governors of the Imperial Cancer Research Fund was held at the Royal College of Surgeons on April 18, when the 42nd annual report was presented by Prof. H. R. Dean, the chairman of council. Appropriate mention was made of severe personal losses which the Fund has suffered in the death of Sir Humphry Rolleston, who was chairman for 16 years; Sir John Ledingham, who was a visiting research worker in the laboratories of the Fund; and Viscount Dawson of Penn, Sir Cuthbert Wallace, and Sir Thomas Barlow, all of whom had been closely connected with the Fund for a long period. The Fund during last year received in legacies over £48,000, a larger sum than in any previous year in its history. Subscriptions also increased by £827. Viscount Halifax was re-elected president and Sir Holburt Waring treasurer.

Scientific Work

A report was made on the work done by the seven members of the scientific staff and the four visiting research workers. Further study has been made of the retarding effect of sulphur inhibitors on carcinogenesis. Mr. H. G. Crabtree, working on the induction of tumours with pure chemical substances, has produced evidence that aldehydes and a number of other substances which specifically lower sulphur metabolism in cells cause not only a retardation but in certain conditions a reversal of the carcinogenic action of benzpyrene and dibenzanthracene.

Extensions of these observations are in progress, grouped around the central idea that chemical carcinogens, or their products, exert their influence through sulphur linkages in the cell.

Work has also been continued on the stimulating effect of wound healing on tumour development in mice. When papillomas and cancers appear in the scars of skin wounds it is rather natural to regard them as a consequence of the stimulus of healing, but there is no measure of the extent to which they may be ascribed to chance and to such stimulating action respectively. When tested it was found that more than half the tumours which appeared on scars did so entirely by chance, and the difference is insufficient to enable the remainder to be ascribed to stimulation. But the possibility that wound healing can in fact overcome refractoriness towards tumour development when this is due to latency of neoplasia is not ruled out. Some work suggests that multiple injuries are more effective than a single injury in overcoming this refractoriness, and that repeated excision at the same site may result in a number of localized tumours significantly greater than that due to chance alone.

The factors concerned in sarcomatous transformation during the transplantation of mammary cancers in inbred strains of mice have been investigated. So far as the work has gone the results emphasize the significance of the stimulation of fibroblastic growth by the carcinoma cells and the survival of the stromal cells owing to their being of the same genetic constitution as the cells of their new hosts. Another subject of investigation is the action of stilboestrol on induced prostate tumours in mice. When stilboestrol is applied at the time of tumour transplantation the growth of the tumour is retarded, or even completely inhibited, but when it is given after a palpable tumour growth has appeared it has been found to have no effect.

Hormonal Stimulation

Prolonged oestrogen treatment has been found to produce in the rat a tumour-like enlargement of the anterior lobe of the pituitary gland, but in the guinea-pig and the rabbit it has not this effect, while in the hamster the reaction takes place in other parts of the gland. It was thought possible to combine the stimulus provided by excess of oestrogen with some other hormonal change affecting the gland, the objective being to overload the physiological reactions of the gland in order to alter the purely hyperplastic character of the resulting growth and perhaps to reach a reaction of true malignant and invasive nature. Thiourea offered an easy method of physiological stimulation of the pituitary body, and by combined treatment with oestrogens and thiourea it is possible to submit the anterior lobe of the pituitary to two different stimuli of a physiological character—namely, absence of thyroxine and continuous presence of oestrogenic hormone.

Accordingly experiments, which are still in progress, have been tried out on rats. Thiourea (in the drinking-water) has been administered to animals in which stilboestrol pellets had been implanted, and it has been found that the character of the pituitary growths differs essentially from those treated with oestrogens alone. The results so far have been partial, but in at least one of the rats growth was able to invade the brain extensively. The cytological character of such tumours differs also from those produced only by oestrogens. In oestrogen-produced enlargements the hyperplasia consists only of chromophobe cells; in these experiments a remarkable abundance of acidophil cells is produced in the growth. It is considered that this effect may help in clearing up the doubt as to which cells are responsible for the production of thyrotropic hormone, but at present all that can be said is that the growths differ essentially from those produced by oestrogens.

R. A. Nelson and L. Duncan (*Bull. Johns Hopk. Hosp.*, 1945, **75**, 327) record their observations on 10 cases of acute syphilitic meningitis treated with penicillin. The immediate results were excellent from both the clinical and the laboratory aspects. Though penicillin did not appear in the cerebrospinal fluid even after repeated intramuscular injections, the drug was effective when given intramuscularly. No clinical relapse occurred. The treatment varied from 600,000 to 4,000,000 units in any one patient and the duration of treatment from 7½ to 11 days.

Reports of Societies

SCRUB TYPHUS

In a lecture at the Royal Institution entitled "Natural History of Scrub Typhus: A Problem on the Asiatic Front," Prof. P. A. BUXTON, F.R.S., said that the work of the last ten years on diseases of the typhus group had permitted us to understand certain sides of them much more clearly. It was now known that there was one disease of this group widely spread in Eastern Asia, transmitted from rodents to man by what we should call harvest mites. It should be known as scrub typhus or alternatively as mite-borne typhus. No good general account of it, particularly from the entomological side, was available in print. The disease was of considerable imperial importance.

The natural history of the disease was complex, and it might be best to approach it by indicating what was known about the so-called "harvesters" of Britain and Northern Europe. They were the larvae of *Trombicula autumnalis*; the so-called "chiggers" of North America were closely related. These larvae, a fraction of a millimetre long, attached themselves to the skin of rodents, man, birds, etc., and held on for several days. They dropped into the soil, moulted to become a nymph, moulted again to become an adult, and the female then laid eggs. Knowledge of the life history in the soil was fragmentary, but it seemed to be established that the nymph and adult were vegetarian or that they fed on decomposing organic material. It seemed that there was only one species in Britain, and there was probably only one generation in the year. The rabbit and the bank vole were important hosts of the larva. Larvae were common on the bank vole in late summer and autumn and after that diminished through the winter, to fall to a minimum in June. The species occurring in Britain seemed to be localized to light soils, particularly those which were chalky, and the distribution was often extremely patchy. It seemed probable that by applying methods worked out for problems of soil entomology much might be learned about the biology of this creature. In attaching itself to the mammal, the larval *Trombicula* ejected a digestive juice which caused an area of hyaline degeneration: this often took the form of a sharply defined column, vertical to the skin. Nothing was felt at the time when the larval mite was puncturing the skin, but some hours later irritation developed in some, but not all, human beings. The irritation might be quite serious, particularly to troops living in the field.

In South-East Asia there were many genera and species of trombiculid mites, and the larvae of a considerable number of them attacked man. Rodents were certainly important hosts, and the natural history of scrub typhus was very complex because of the variety of rodents in that part of the world. The larvae were important because they transmitted the infectious agent producing the disease called scrub typhus. The earlier work was mostly Japanese and showed that the larva of *Trombicula akamushi* fed normally on voles (*Microtus*), on alluvial soils. It transmitted infection from vole to vole or vole to man. As the mite fed on a mammal only once in its life history, the infection must be hereditary, and the virus had actually been recovered from wild adult mites. A similar or identical infection, always transmitted by larvae of *Trombicula*, was known or believed to occur in the great triangle bounded by Japan, New Guinea and Northern Queensland, Ceylon, and the Maldives. Within this great area the disease might occur under exceedingly different environmental conditions—e.g., in equatorial forest, or in grassland, or on barren islets and atolls.

In man the disease was generally serious. There was a small ulcer at the site of attachment of the larval mite, accompanied by high fever. The disease was widely distributed over the area of South-East Asia, and as men were living and fighting in jungle it had proved much more common than generally expected. It tended to be highly localized and to produce occasional outbreaks with a very variable but serious death rate.

Correspondence

Institutional Maternity Service

SIR,—The letters on women in labour by Dr. John Elam (April 7, p. 495) and on infant deaths by Dr. S. H. Waddy (April 14, p. 529) to my mind both point in one direction—namely, to the need for encouraging a home maternity service, and to discouraging institutional maternity provision. At present, particularly since the wartime establishment of maternity homes for the wives of Service men, the tendency has been towards more institutional maternity provision with, I believe, the following unhappy results.

(1) Owing to the shortage of nursing staffs in maternity as in other hospitals the woman in labour is only too often left alone "to get on with it," with or without an analgesic apparatus. This is a great cruelty to a young woman undergoing the tremendous experience and ordeal of her first confinement. She is a stranger in a strange place, attended through her many hours of labour by a series of nurses, who, however kindly intentioned, can only regard her as a number—bed or ward. At home she would undergo her great experience in the care of one nurse, probably the district nurse, to whom she is already known, and as Mrs. X. of Z. Street. It is sometimes stated that the presence of the patient's family, anxious as they inevitably are, intensifies the patient's own anxiety and consequently the difficulty of her labour. But is it not more likely that the patient draws comfort and reassurance from the nearness of interested people?

(2) Dr. Waddy refers to the harmful, even under certain conditions fatal, results of the institutional custom of rolling new-born babies into tight little mummies with arms pinioned. The justification for this is said to be that it induces sleep by the sense of security it gives by reproducing as closely as possible the non-stimulating intra-uterine environment. Even where physical damage is not done, may not the subsequent sleep represent not so much a reaction to a feeling of security as a withdrawal from life in the face of frustration of normal impulses to muscular activity and self-defence—a first withdrawal from a too difficult reality, setting a pattern for later regressions and withdrawals in the face of difficulty, and producing an inhibited and introverted personality.

(3) Another characteristic of institutional maternity not referred to by Drs. Elam and Waddy is that the baby spends most of the first ten days (or more) of its life away from its mother, who is allowed to hold it only at feeding times, and then frequently in the presence of a third person, the well-intentioned but officious nurse directing the whole process and often producing thereby an anxious mother and an agitated, lethargic (=withdrawn), or even shocked baby. (See *The Nursing Couple*, by Dr. Merrill Middlemore.) The late Dr. Ian Suttie (*Origins of Love and Hate*) postulated an inherent social instinct, and believed that the first personal relationship is spontaneously sought by the suckling with its mother. The development of this—all-important for the subject's future happy adjustment in life—is suppressed and crippled at its very beginning by maternity-home methods.

When the baby is not a first one a confinement at home is also far less upsetting to the "dowager baby." It is upsetting enough to have mother upstairs in bed and absorbed in a newcomer, but at least she has not disappeared, apparently for good. One little girl refused to accept her mother on her return with the new baby as the same one who went away. She said, for instance, "My other Mummy used to have a blouse like that." One can surmise what a shattering disturbance of her sense of security this acceptance of a complete loss must have meant.

Hygiene and asepsis have been allowed to outweigh all else in the modern development of maternity techniques, with the result that the profound significance of the personal experience and emotional development of the human beings involved has tended to be overlooked. And even as regards hygiene and asepsis, are the good results commensurate with the provisions made and the precautions taken? Is it not the case that more cases "go septic" in maternity homes than in patients' own homes where the mother has gained a fair immunity to her local germs? Personally, I know I have been happier conducting a confinement and puerperium in the patient's home than in hospital or maternity home, in spite of the fuller provision of facilities and the smaller demand on one's time in the latter. Why? Because the *psychological* atmosphere is more normal, more friendly and easy, and much more stimulating. All of us were happier, I believe—patient, nurse, and doctor—and if that was the case, then it was surely happier and healthier for the newcomer as well.—I am, etc.,

Peppard, Oxon. LAURA HUTTON.

Civilian Mass Radiography

SIR,—I would like to compliment you on the critical but fair review in your leading article on civilian mass radiography (April 14, p. 521). It seems to me that the criticisms which you raised against civilian mass radiography in general do not apply to the Nottingham Corporation Mass Radiography Unit, as this unit is run on slightly different lines from those laid down by the Ministry of Health in the Advisory Report on Mass Radiography.

The City of Nottingham's unit has the Chest Radiography Centre as its home base. The ground floor at this centre is devoted entirely to mass radiography. This does not mean that the *x*-ray unit is completely static, because the unit is transportable and is taken to factories of sufficient size to justify this step. The first floor at the centre is equipped as a modern chest diagnostic out-patient clinic, and deals with the abnormal cases discovered by mass radiography. Equal attention is paid to all diseases of the chest, whether tuberculous, non-tuberculous, or cardiac. All abnormal cases are seen at this centre and are fully investigated here both clinically and bacteriologically, and those that require in-patient investigation are referred for admission to the sanatorium or general hospital, as the case may be.

I would like to draw attention particularly to the special out-patient clinic which is held at the centre for the symptomless minimal tuberculous cases. These cases are under the personal supervision of the medical director, and are referred to the tuberculosis officer only if the lesion should spread or there are definite indications for sanatorium treatment. In this way the symptomless minimal case is kept under the supervision of one observer and renders "follow-up" investigation an easy matter. Further, this method lends itself to the application of research work in these cases. I find from experience that the patients in this city are most co-operative; that many are willing to attend our chest radiography clinic, without being labelled tuberculous, who would refuse to attend the tuberculosis dispensary for this very same reason.

In Nottingham close co-operation exists between all the branches of chest work for the rapid disposal of those cases detected by mass radiography. It is useless detecting early cases of pulmonary tuberculosis unless something is done for them, and with a minimum of delay. As a rule cases referred from the mass radiography unit are seen by the tuberculosis officer at the dispensary within *one* week of their clinical examination at the Chest Radiography Centre. Early cases of pulmonary tuberculosis which need priority admission to sanatorium have been admitted to sanatorium within *two* weeks of their being seen by the tuberculosis officer. It is no exception for a patient to be admitted into the sanatorium within three to four weeks of the first clinical examination after mass radiography. Detection of early cases requires early disposal.

It is my intention, as medical director of the Chest Radiography Centre, to visit the sanatorium at regular intervals in order to "follow up" the cases diagnosed through our mass radiography unit. Already we have held such a session, which included the medical superintendent of the sanatorium, his assistant medical officer, and myself. Cases were fully discussed, with profitable results to all concerned. Only in this way can we hope to learn the most about these symptomless tuberculous lesions. The organization for the disposal and treatment of the non-tuberculous case is just as comprehensive.—I am, etc.,

Chest Radiography Centre,
Nottingham.

A. E. BEYNON,
Medical Director and Physician.

Sulphonamides in Measles

Sir,—I was very interested in the observations recorded (April 21, p. 567) by Dr. J. Frankland West. He writes that he would be interested to know whether similar results have been experienced.

I have just experienced a similar successful result by treatment with sulphadiazine. This was given to a boy aged 5 years when I found him to have a temperature of 100.5° F., with no physical signs, and it was given in the hope that, should some serious condition develop that would later need such treatment, a good start would have already been made. I did not then have reason to suspect developing measles, which did come on after three days. The attack was surprisingly mild, with very slight cough and no inflammation or any soreness of the eyes; there was a very sparse rash, and the whole condition cleared up within 48 hours.

This child's sister, a year older, developed measles. She was first seen by me when the rash and other symptoms made the diagnosis obvious. At that time it did not occur to me that the chance giving of sulphadiazine to her brother had any beneficial effect on the attack of measles, and she was not given this drug; she had a most severe attack, with a higher temperature, very sore discharging eyes, a very profuse rash, and a marked lengthening of the attack.

More extensive statistics on the effect of this drug on measles would, I consider, be most useful.—I am, etc.,

London, N.W.1. M. D. Ripka.

Sir,—I should like to testify to the highly beneficial effects of sulphathiazole in measles. In the recent epidemic, in which I saw some 106 cases, I gave it at first to the more severe cases, and its effect was so striking that I began giving it to nearly all cases, with equally almost astonishing results. The epidemic though heavy was only mild, in that spring measles is generally milder than the winter type.

I am convinced that, pneumonitis or no pneumonitis, sulphathiazole is also a "specific" for measles. The usual complications, particularly otitis media and pneumonia, thanks to sulphathiazole, worked out at less than 6% with no deaths, while the duration of the illness was curtailed by half. I wish to emphasize that, while the majority of cases were mild, there were many severe cases too.—I am, etc.,

Kennington. H. J. Powell.

Sir,—I treated nearly all my cases during the recent epidemic with sulphanilamide and got excellent results. I gave sulphadiazine to one patient, whom I suspected was developing measles, merely because a friend who was with me (we were stopped on the road on Easter Monday while on our way to see a patient of my friend) had some sulphadiazine in his car. The child did develop measles, and I switched over to sulphanilamide with the usual good results. This may interest Dr. J. Frankland West, whose letter has prompted this.—I am, etc.,

London, W.11. Ralph Jones.

Sir,—Dr. Frankland West's experience with sulphadiazine in measles prompts me to send in mine. A couple of years back I had fourteen cases in a girls' residential school. It was a severe epidemic of measles, to judge only from the temperature, which ranged between 103.5° F. and 105° F. at the peak of the illness, and there were no complications, due undoubtedly to the same sulphadiazine. The ages of the patients were from 5 to 15; all of them were given 1 g. of the drug as an initial dose, followed by 0.5 g. four-hourly till the temperature was normal. In no case was treatment begun before the diagnosis of measles was established before the appearance of the rash. In every case except the 5-year-old patient the rash had faded and the temperature dropped to normal in 48 hours. In the only resistant case this took 96 hours. The patients, moreover, suffered little "illness" once under the influence of the drug, and returned to a normal diet more quickly; in fact their worst phase was while waiting for the rash to appear.

This does raise the question of the period of isolation in such cases, and also of the immunity they developed. There was no question of their well-being. A factor strongly brought out was the good effect on their skins. Those who had previously suffered from acne seemed to have procured a new skin!

A child of 6 months, seen last month with a temperature of 102° F., a persistent cough, and a rash, and also diagnosed as suffering from measles by another medical man, lost rash, temperature, and cough on 0.15 g. sulphaguanidine twice a day for a period of 3 days. This latter drug I have found extraordinarily effective in this dose 2-hourly for the influenza which seems to correspond clinically with the "genuine" disease and which responded poorly to both sulphathiazole and sulphamezathine.—I am, etc.,

Hereford. T. Pires.

Sulphonamide Therapy in Otitis Media

Sir,—I have read with great interest as a country practitioner your correspondence on sulphonamide therapy in otitis media following the letter of Mr. A. R. Dingley (March 24, p. 422). Does he yet realize that the vast majority of cases we general practitioners see are at an early stage, which he, as a consultant, will rarely be called to see? I find that the pain is almost invariably relieved after the second dose of the drug, but the drum must be inspected frequently and carefully if the occasional case which proceeds to suppuration and requires timely paracentesis is to be detected. If this routine is carried out competently with an adequate auriscope, and some means of testing hearing, I regard the treatment as absolutely safe.

Parents are beginning to realize now that we can do more than give anodynes if called to treat their children in the early stages. Furthermore I find that if an attack can be aborted early there is no longer that increased liability to subsequent attacks in the presence of nasopharyngeal infection, which invariably follows a first attack when suppuration and discharge have taken place.—I am, etc.,

Bakewell. Sinclair M. Evans.

"Predisposition" to War Neuroses

Sir,—Dr. Frederick Dillon in his letter (April 21, p. 570) says that in my article (March 31, p. 444) it is suggested that "predisposition to breakdown under war conditions can be correctly estimated from the occurrence of nervous and mental illness in the family and personal history of the patient and from a poor work record." I would not dare to suggest that it is possible to estimate *correctly* when a patient is likely to break down even under stress of war. Many patients fulfil these factors as to predisposition and are able to withstand the shocks and stresses of war. On the other hand, if these factors are to be ignored why do the great majority (I cannot give the exact figure) of the admissions to this neurosis centre satisfy these conditions?

Surely the control group can be supplied by those patients who are admitted to the surgical side and who show no evidence of neurosis and no predisposition in the form mentioned. Even some of those with *no* predisposition break down if the stresses are severe enough.

I agree with Dr. Dillon that a number of neurotics have made excellent soldiers, but these are the exception rather than the rule. I also agree that mildly obsessional persons often have excellent work records, but when they develop obsessional neuroses the work does suffer as a result. Abnormal personality traits alone of whatever type do not constitute predisposition, but when added to the other factors mentioned, surely the risks of a neurosis developing in such an individual are considerably increased when exposed to the stresses of war.—I am, etc.,

Sutton Emergency Hospital. Louis Minski.

Malaria in West Africa

Sir,—I was most interested in the article by Squad. Ldr. D. G. Ferriman on the diagnosis of malaria in West Africa (March 10, p. 328), and especially the section on subclinical malaria. This condition and that of clinical malaria—i.e., cases in which positive blood films are not found—are forming the majority of the cases seen out there to-day.

Although no reference is made to the period during which the data were obtained, it appears that it would be before 1944, because during that year the suppressive dosage of mepacrine was increased from 0.2 g. twice weekly to 0.1 g. daily. With this change of dosage there has been a very definite change in the relative incidence of the three types—M.T. malaria, clinical malaria, and subclinical malaria—as reported in the article, and it is this fact that has led me to write this letter, which is not intended as a criticism of a very excellent article.

In the early period of 1944 I was fortunate enough to conduct an experiment with the increased suppression dose. The station was divided into two equal groups, each barrack block being divided equally, both numerically and, so far as possible, by trades, as night workers (e.g., wireless operators) were found to have a greater incidence than other trades. One half were then given the old dose of 0.2 g. mepacrine twice weekly, and the others were given 0.1 g. for six days a week. Unfortunately the experiment was terminated some two months later, before really reliable statistics could be obtained, by the introduction of a suppressive dose of 0.1 g. daily to all personnel, but there were definite indications that the increased dosage reduced both the primary and secondary attacks of malaria considerably. More marked, however, was the reduction in the number of positive slides obtained. These indications were more than confirmed with the introduction of the daily suppressive dose of 0.1 g. mepacrine. Positive blood films became much less frequent, and in fact furnished some indication of the state of antimalaria discipline on the station. If more than 50% of cases were found to have positive slides, it could be assumed that discipline was lax. I also found the examination of blood films of value in assessing whether or not a patient had been taking his suppressive mepacrine. In most positive slides parasites were relatively scanty, and the rings usually poor, woe-begotten affairs. If a textbook appearance was found it was almost certain that suppressive mepacrine was not being taken regularly, and in most cases a direct challenge to the patient would substantiate this fact. To obtain 90 positive slides out of 136 consecutive low-fever cases, as reported in the article, would be most exceptional to-day.

Regarding clinical features, temperatures of more than 102° F. are rarely seen in my experience. Splenomegaly was not found to be anything like as high as the 25% quoted in the article; it occurred in less than 10% of the cases I saw, but tenderness over the spleen and under the left costal margin was very frequent. The description of the anomalous behaviour of malaria resembling other diseases, and also that of subclinical malaria, was greatly appreciated, as these are the types of malaria most commonly presenting themselves to a Service medical officer. In this connexion I found that a careful history of the two days before reporting sick was of great value, especially in those cases where the temperature was between 99 and 100° F. In nearly all cases of clinical and subclinical malaria the following history could be obtained, in most cases without the use of leading questions.

There would be the development of lassitude, and a feeling of over-tiredness during the afternoon, and by evening there would be a definite anorexia associated with varying degrees of headache. Usually the headache was occipital and slight. This would be followed by a poor night's rest, but on rising the following morning the headache would have disappeared and the appetite returned; there would still be a disinclination for work. Work would be begun, however, and during the forenoon the headache would recur and increase in intensity throughout the afternoon. The anorexia would return, and if the man did not report sick at this time he would usually retire early without his evening meal. He would have a good night's sleep—often described as "a very heavy sleep"—but when he awoke the headache and anorexia would be marked, and he then usually reported to the medical officer. The remission of headache and anorexia on the first morning with a return of the symptoms later in the day was not found in cases of upper respiratory tract infections, between which and clinical malaria a differential diagnosis has most frequently to be made.

A good case history was found to be of increasing importance in the diagnosis of malaria as found in the Service to-day, as the classical signs and symptoms of high temperature, rigor, enlarged spleen, and positive blood films are rarely seen. It is more than likely that these will be even less often found with the introduction of this new scheme whereby all personnel shall have had 1.75 g. of mepacrine before landing in Africa, or shall be given additional doses of 5 gr. quinine daily until they have had this amount of mepacrine. I personally had had only 0.4 g. prior to landing and this appeared to be about the average amount of mepacrine taken before landing in 1943 and early 1944. As a result the malaria incidence was relatively high in personnel during the first two months on the coast, because there was not a sufficient concentration of mepacrine in the tissues to afford protection, and it was in these cases that I found the highest percentage of positive slides.—I am, etc.,

J. C. HUTCHINSON,
Flight Lieut., R.A.F.V.R.

Treatment of Cerebral Malaria

SIR,—In the *Journal* of April 21 (p. 560) the leading article on pathogenesis of cerebral malaria, and on page 567 the letter on adrenaline in the treatment of malaria by Lieut.-Col. D. C. Macdonald, claim attention. In spite of statements to the contrary, cerebral malaria is nearly always due to *Plasmodium falciparum* infections, neglected, unrecognized, masked, ineffectively treated, or misdiagnosed. Special strains of *Plasmodium falciparum* are particularly liable to produce this complication —e.g., the variety current in the region of Kermanshah. The absence of demonstrable malaria parasites in the peripheral blood not infrequently makes diagnosis a bit harder. Blood films of venous blood, or liver, spleen, or sternal puncture, are of value occasionally, but often are disappointing. The erythrocyte sedimentation rate can be helpful. Intravenous saline, which can be used as a vehicle for quinine bihydrochloride or for adrenaline, is usually a necessity: these drugs may be injected with a hypodermic needle into the rubber tubing of the saline infusion set. It is necessary to warn against the injection of quinine bihydrochloride solutions into the rubber tubing of a set giving citrated blood, since troublesome clotting will ensue. Even after intravenous quinine it is advisable to test for quinine any sample of urine that can be obtained.

Patients who remain obstinately unconscious after repeated intravenous injections of quinine are encountered from time to time among the cases brought in too late for effective therapy (as reported by Col. A. W. D. Leishman and Capt. A. R. Kelsall, *Lancet*, Aug. 19, 1944, p. 231) and confusion with the prolonged coma of hyperthermia is a possibility which nearly always has to be considered. The modern Army system of prophylaxis (one tablet of mepacrine a day) will prevent blackwater and cerebral malaria, not completely perhaps, but very nearly. Idiosyncrasy to this drug may be rare, but does occur. Prophylactic quinine may not be absorbed, and urine tests for quinine—or the mixture of methylene blue with the preparation used—are advisable. Inspection of the urine of a patient taking mepacrine or "blued" quinine is often enough, but is a wise precaution. In the "shock-like" condition of malarial coma, intravenous adrenaline may release adrenocortical hormones (Voge), perhaps an explanation of the undoubted benefit which follows.

Spleen contraction for convalescents taking anti-relapse courses may be encouraged by two-mile walks, cold baths, sunbathing, swimming, hill-climbing, aeroplane trips, and breathing carbon dioxide from a mask as well as by injections of adrenaline, effective as this procedure may be. The spleen is not the whole story: capillaries in other abdominal viscera, the lungs, muscles, glands, and skin all may harbour the parasites of relapse in closed sections opened by exercise, etc.—I am, etc.,

FRANK MARSH,
Pathologist, A.I.O.C.

Intestinal Obstruction by Gall-stones

SIR,—I have read the article by Mr. Maurice Lee on intestinal obstruction by gall-stones (April 21, p. 555) with interest, because in December, 1944, within a few days of each other I encountered and operated upon two cases which occurred in my own general practice. Both cases were in elderly females. Case 1 was a typical case of acute intestinal obstruction. The gall-stone was lodged near the end of the ileum. Case 2 was unusual. The patient was fat and florid and suffered from myocardial degeneration, and as a result of clinical and radiological investigation I diagnosed a probable "ring" stricture in the pelvic colon. With the intention of performing a colostomy I opened the abdomen through a left grid-iron incision, and was agreeably surprised to find a large gall-stone (rather less than the size of a golf-ball) lodged at the pelvi-rectal junction and easily "milked" upwards into the pelvic colon and removed through an incision in the bowel wall. The patient made a good recovery and returned home much improved by her enforced rest and reduced diet.—I am, etc.,

Dunfermline. A. Campbell MacEwen.

Gonorrhoeal Arthritis

Sir,—In September, 1935, while in India, I published in the *Lancet* the results of my work on fresh and chronic cases of gonorrhoea treated by pyretotherapy, using T.A.B. vaccine. I have since mentioned those findings in the *Journal* of Oct. 21, 1944.

I should now be glad if you would afford me space to publish the results of a chronic case of gonorrhoeal arthritis of two years' duration, in which the patient had persistent pain and could not move without a stick but is now able to do so without any pain after a period of treatment of only a fortnight. In this case I used a *B. coli* vaccine.

History.—Fresh infection 1927. Treated at a V.D. clinic for six months, then discharged as cured. In March, 1943, suddenly developed arthritis in both ankles, which became very tender, painful, and swollen. Was in bed for 5 weeks and has had to use a stick since. He is still attending a V.D. clinic. Since that time he has developed pain and stiffness in both shoulders and in the spine. His feet are flat, his toes over-ride each other in their deformity. This man was once an athlete and runner, with well-formed feet.

Present Condition.—He is unable to walk without a stick. Severe pain on movement in both ankles. Flat-footed and toes pointing laterally and over-riding each other. Pain and stiffness in shoulders, and similarly in spine, dorsal and lumbar regions. He is unable to bend down and pick up objects from the floor without going down on his haunches. Knees slightly swollen and painful.

Treatment began on *April 4, 1945, 1st injection.* 50 million organisms per c.cm. given intravenously. Within two hours he developed a rigor, felt cold, then hot, and within four hours his temperature rose to 103° F. Later he sweated profusely, and by next morning he had a normal temperature. He stated his pains felt easier.

April 6, 2nd injection. 100 million organisms in 1 c.cm. intravenously. Similar type of reaction. Temperature, 104°. Normal next morning. Pains only slight on movement.

April 8, 3rd injection. 200 million organisms in 1 c.cm. Similar reaction. Temperature, 105°; normal next day. Only slight pain in the left ankle on movement; none in right. Stated the left was always the worse of the two. Shoulders and back were free from pain and stiffness. Slight headache next morning. States he feels very fit and better than he has been for a long time—ever since he was crippled.

April 10, 4th injection. 400 million organisms in 1 c.cm. Similar reaction and temperature. No pains felt in ankles on active or passive movements. Able to bend down and pick up objects from the floor, and able to walk without the aid of a stick. Very slight pain in left ankle.

April 12, 5th injection. 1,000 million organisms in 1 c.cm. Severe reaction and headache persisted next morning. No pains felt in knees, ankles, shoulders, or spine. No pain in ankles on walking. Crêpe bandages applied during the day.

April 14, 6th injection. 2,000 million organisms in 1 c.cm. Very severe reaction, and persistent headache next morning. No pains whatever in any joints. All stiffness of shoulders and back gone. States he feels like a new man. Has lost the drawn and haggared look that comes with persistent pain over a long period. Advised to use elastic ankle socks or crêpe bandages, and to "go easy" for a while. Also advised to use his stick when walking any distance. No swelling of knees.

April 18, 1945. Came to see me to-day, looking very happy and contented. Said he had walked two miles to-day, and felt none the worse.

In view of the long period of pain with its crippling effect and the rapidity with which this was relieved, the case is considered of special interest, with the hope that similar cases may be given the opportunity of this treatment, which can be carried out at the patient's home or in a hospital. The patient's gratitude and buoyancy on being relieved of his agonies are a reward.—I am, etc.,

London, S.W.16. A. H. Bartley.

Inguinal Hernia

Sir,—The *Journal* of March 3 containing Mr. Percival Cole's article (p. 296) on inguinal hernia in the Merchant Navy has just reached me. I would like to offer, unfortunately belated, comment.

Mr. Coles appears to advocate a return to the generally discarded filigree operation as an alternative to other forms of herniorrhaphy. The arguments are based on these figures: 4 recurrences out of 130 filigree operations (3%) and 12 "met with" out of another series of 448 filigree operations (2.8%), which are compared with a recurrence rate of over 12% as representative of British surgery as a whole. The figure of 12% is probably a fair one and substantiated by a series of cases carefully followed up, such as that of Max Page and McPherson on policemen operated upon at St. Thomas's Hospital.

I would submit that the comparison is an unsound one on two grounds: (1) Institutional figures for a large number of surgeons are not comparable with those of an individual. The latter, if sufficiently enthusiastic to publish his results, is probably a virtuoso in his technique and unrepresentative of the "average" surgeon. (2) There is no mention of a systematic follow-up in which a number of patients were traced and examined at a definite interval after operation. Only recurrences "met with" are mentioned. It seems unlikely that anything like an adequate "follow-up" could have been exercised on clinical material consisting of men in such a nomadic and hazardous occupation. Even under optimum conditions the failures, the dissatisfied patients, are always the harder to trace. The more complete a follow-up and the nearer to 100% it becomes the more difficult it is to trace defaulters and the more sharply rises the recurrence rate.

Mr. Coles's conclusion that "the figures cited clearly suggest that the recurrence rate attached to this operation is remarkably low" appears unsubstantiated and does not show that a return to the filigree operation is the answer to this still unsolved problem.—I am, etc.,

Takoradi. J. B. Kinmonth,
Squad. Ldr., R.A.F.V.R.; Surgical Specialist.

Intravenous Pentothal in Placenta Praevia

Sir,—I note that Prof. S. J. Cameron (April 14, p. 532) places intravenous pentothal first on his list of suitable anaesthetics "in cases of placenta praevia where the patient's condition is critical." This is very interesting in view of the fact that most surgeons and anaesthetists have come to the conclusion that pentothal is a dangerous anaesthetic for severely shocked cases unless given very carefully by an experienced anaesthetist. This conclusion has been completely confirmed by those engaged in the treatment of war casualties, and especially by the Pearl Harbour "pentothal disaster."

If pentothal has any real advantages in Prof. Cameron's cases may I suggest that they are as follows: (1) The quick induction given by pentothal gets the patient ready for the surgeon in a shorter time, when relaxation of the abdominal muscles is not required, than can be obtained with any other anaesthetic. This time factor may be of great importance when the haemorrhage can be stopped only by surgical intervention. (2) When anaesthetizing badly shocked cases with pentothal it is usual to administer pure oxygen throughout the operation. This would obviously be of benefit to such exsanguinated cases as women who have suffered severe bleeding from a placenta praevia.

Finally, I should like to point out that most anaesthetists believe that, chloroform apart, safety lies in the skill of the administrator rather than in the agent.—I am, etc.,

Harrogate. James Campbell.

Immunization against Tuberculosis

Sir,—I wish to draw attention to a matter that should be of the utmost interest to the Medical Research Council.

So far as is known it seems that any attack of an infectious disease is followed by either death or recovery. When recovery takes place, antibodies can be demonstrated in the blood. This fact has been taken advantage of in various ways—for example, animals can be infected with certain germs and made to produce antibodies in their blood. These antibodies have been used in the treatment of the particular disease in a human being. Bacterial poisons or even bacteria themselves having had their virulence demonstrated have been injected into human beings and thus produced immunity to the disease in question.

Why cannot we do this in the case of tuberculosis? Why is tuberculosis an exception to the rules governing all other infections? This is probably the most important question before modern medicine in this country. The amount of suffering and the economic loss due to tuberculosis in any one year are enormous. It seems to me essential that work should be started on the question of immunity to tuberculosis. Very little has been done in this country or indeed anywhere else on the subject, yet the problem cannot be insoluble; it only requires sufficient work to elucidate it. Think what it would mean if tuberculosis could be prevented as easily as, say, diphtheria. But for some reason the profession all over the world seems to have accepted the position that tuberculosis is unique, and is content to spend its energies in repairing its ravages rather than in scientific, biological prevention.

I feel that this is a subject eminently demanding the attention of the Medical Research Council, and although the problem may seem insoluble, I am convinced that it is not so, and I can conceive of no greater benefit which the medical profession could confer on mankind than that it should succeed in solving it.—I am, etc.,

Crowthorne, Berks. SYDNEY GORDON TIPPETT.

⁂ A leading article in the *Journal* for Dec. 4, 1943 (p. 716), reviewed the history and progress of immunization against tuberculosis in man and animals.—ED., *B.M.J.*

Artificial Respiration

SIR,—Many articles on artificial respiration have appeared from time to time in British medical journals recently, concerned chiefly with the relative merits of the well-established manual method of Schäfer and a comparatively new mechanical method introduced by Eve.

Considerable research in this subject was conducted some years ago in the department of physiology, University of Toronto, under the late Prof. J. J. R. Macleod, by Urquhart and Noble,[1, 2] and for the Hydro-electric Power Commission, Province of Ontario, by Mr. Wills Maclachlan.[3, 4] A definite relationship between the application of artificial respiration in cases of asphyxia and ultimate recovery was established, the essence of which was *time*. This relationship was so striking that it formed the basis of all instruction in artificial respiration in hydro-electric first-aid crews, life-saving societies, Red Cross and St. John Ambulance Brigade units, etc.; this consisted of the application *on the spot, with a minimum of time loss, of some form of manual artificial respiration,* the optimum of which was considered to be Schäfer's. All teaching was directed towards dispelling from the mind of laymen the illusion that any machine, such as a pulmotor (or now a "rocker"), was a panacea for which one only had to wait, usually beyond the time interval in which life may be restored, and all would be well, and to establish firmly in their minds that any person by his own efforts is capable of performing artificial respiration, the success of which depends entirely on its immediate application.

It cannot be too strongly stressed that the introduction of any new mechanical method, irrespective of its merits, tends to create in the public mind a dangerous impression and one which would appear to have been entirely disregarded in recent communications. The interval that must of necessity elapse before the commencement of any mechanical device may jeopardize the life of the victim. Once the critical interval has been exceeded (and this has been determined experimentally on animals and by case reports of human beings: *J. industr. Hyg.*, 1928, **10**, 117) it should be superfluous here to point out that no method whatsoever can be successful.

Certain statements in the letter by Eve (April 7, p. 495), such as "there are many instances of failure of the Schäfer method," and "it fails much oftener than it succeeds," are, in my experience and that of competent authorities, entirely without foundation and actually misleading. One cannot deny that there are failures, but failure should only be encountered when the victim is already dead or moribund and where artificial respiration by any means has not been instituted within the critical time interval (up to six minutes, depending upon the patient's condition and other circumstances).

Eve refers to the toneless diaphragm, which so far, it is admitted, has not been demonstrable radiologically but which is assumed by analogy to exist. It would be of interest to obtain the experimental evidence upon which this assumption is based. He states further that in the rocking method the weight of the abdominal contents pushes and pulls the diaphragm up and down like a piston. He assumes that all air intake into the lungs is governed by the rise and fall of the diaphragm; presumably the expansion and contraction of the chest wall has no effect. He ignores entirely that in Schäfer's method, when the pressure is properly applied over the lower ribs, the thoracic cage is compressed and at the same time the visceral contents press upwards against the diaphragm and venous blood from the splanchnic reservoir is returned to the heart. To state that when the pressure is released these contents remain pressed up into the thoracic cage behind a toneless diaphragm is as ridiculous as it is physiologically unsound.

In all fairness, one must admit that the rocking method may contribute something toward a return blood flow to the heart and lungs, but unless adequate circulation is still being maintained any method is predestined to failure.

No evidence has been adduced so far to warrant altering the teaching of Schäfer's method as the most satisfactory method of artificial respiration.—I am, etc.,

E. CLARK NOBLE.

Smallpox Vaccination: Multiple-pressure Method

SIR,—I read with much interest and approval the account of smallpox vaccination by the multiple-pressure method given by Dr. H. J. Parish (Dec. 16, 1944, p. 781). He states, however, that this method has never been adopted in England. This way of performing vaccination was taught to me during my course for the Diploma in Tropical Medicine in 1936 at the London School of Tropical Medicine and Hygiene, and I have used it ever since with most satisfactory results. Unfortunately I cannot remember which member of the staff at the school demonstrated the method, but I feel it should be known that it was being taught there over eight years ago.—I am, etc.,

J. F. JARVIS,
Medical Officer, Colonial Medical Service,
Morogoro. Tanganyika Territory.

Shall We Nationalize Medicine?

SIR,—Lord Horder's suggestion (April 7, p. 497) of sabotage in connexion with the movement in which Prof. Ryle is interested, and, secondly, his suggestion of Prof. Ryle's doubtful ability to stand firmly on what he believes to be a sound principle, are not complimentary to those of us who agree with Prof. Ryle.

As Lord Horder knows, the medical student hitherto has been taught in the most dogmatic manner to be conservative, and any attempt to put forward any new idea is followed by a shout of "heterodoxy" and a refusal to face facts. The great improvements in medical work are all intimately associated with improvements in the social life of the whole community, and unless medical men are prepared to fall into step with that progress there will inevitably be trouble. As medical men in a country interested in the conditions of India we are made to realize the seriously unhealthy conditions under which the huge population of India is existing, not living, and no improvement in medical work can be hoped for unless there is a complete revolution in regard to the vested interests—such as those of landlords, priests, and financiers—together with a complete rearrangement of medical services. The two rise or fall together, Lord Horder notwithstanding.

Medical men who do their work properly are entitled to adequate remuneration, but unless incomes are so stabilized as to remove anxiety by removal of insane professional competition, we cannot hope that the work will be done as it ought to be done.—I am, etc.,

Swansea. G. ARBOUR STEPHENS.

Prophylaxis of Dysentery

SIR,—A brief note on the use of sulphonamides in preventing the incidence and spread of dysentery in a small community may be of general interest. It is based on the experience of the last 17 years in a mental hospital, and all cases referred to were proved positive bacteriologically.

During the first four years of this period, an average of five new cases of Flexner dysentery occurred each year. Thereafter, in spite of all that could be done by way of cleanliness, isolation, decontamination, and treatment by inoculation, the number of cases continued to increase until the peak year of 1941, during which 52 cases occurred. Various sources of infection were considered and sought for, but by this time I was convinced that the disease was being kept alive and was being spread from patient to patient in the wards by "carriers" of the disease; for though new carriers were constantly being discovered there must always have been a number who were not known. Also, I had by now reluctantly come to the conclusion that dysentery was endemic in the hospital. I admit that this was a confession of failure and almost of despair.

During 1942 sulphaguanidine came into use in the hospital in the treatment of dysentery, and immediately a striking improvement occurred. During that year there were 39 fresh cases, but of these no fewer than 37 occurred *before* July, when treatment was begun, and only 2 occurred thereafter, and, what is more, these 2 are the last on record.

During 1943 it occurred to me to use sulphaguanidine prophylactically, and it was given twice in the year to every patient in the hospital and to all members of the nursing staff who were willing to take it. It was also given to all new patients on admission as a routine procedure. During 1944 the whole hospital was again treated, ward by ward, twice at six-monthly intervals, although there had been no fresh cases. The result is that there has been not a single case of Flexner dysentery in the hospital for more than two years.

Recently an epidemic of Sonne dysentery occurred. It broke out simultaneously in three widely separated parts of the hospital, indicating some common source of infection. A member of the kitchen staff, who lives outside the hospital, came under grave suspicion of having introduced it, but it could not be proved. This epidemic covered a period of twenty-one days, during which the stools of 63 persons reported as passing loose motions were examined. Of these, 30 were proved positive bacteriologically. Every patient suffering from the disease was immediately treated with succinyl sulphathiazole, which is more effective than sulphaguanidine for Sonne dysentery; but it took a week to carry out prophylactic treatment of over a thousand mental patients ward by ward. After this treatment only two fresh cases occurred out of this large number protected, and the two wards concerned were treated again. Since then there has been no fresh case of dysentery and all loose motions have ceased.

To summarize, I think it can be reasonably claimed that Flexner dysentery has been stamped out and that an epidemic of Sonne dysentery severe enough to cause at least 30 cases of infection in 3 weeks and which threatened to spread like wildfire was cut short very quickly. It only remains to protect the hospital from reinfection by the routine administration of sulphonamides to all patients on admission and the old-fashioned "asylum dysentery" will disappear.—I am, etc.,

Herrison, Dorchester. P. W. BEDFORD.

The National Loaf

SIR,—*Humphrey Clinker,* Smollett's last novel, published in 1771, contains the following remarks (Everyman's Library, 1943, p. 114):

> "The bread I eat in London is a deleterious paste, mixed up with chalk, alum, and bone-ashes; insipid to the taste and destructive to the constitution. The good people are not ignorant of this adulteration; but they prefer it to wholesome bread, because it is whiter than the meal of corn: thus they sacrifice their taste and their health, and the lives of their tender infants, to a most absurd gratification of a mis-judging eye; and the miller, or the baker, is obliged to poison them and their families in order to live by his profession."

—I am, etc.,

London, E.3. ELI DAVIS.

Flour in the Loaf

SIR,—Having read Sir Ernest Graham-Little's letter (April 14, p. 530), I think your readers should be correctly informed on the technical points mentioned. I refer to his statement that home-grown wheat is the only source of wheat germ, since, he says, the germ is removed from imported wheat in the country of its origin. The main argument of the letter is indeed based on this supposition.

As one who analyses practically every boat-load of wheat arriving in this country, I must point out that the statement made in Sir Ernest Graham-Little's letter is completely incorrect. The germ is not removed in the country of origin but arrives here as a constituent part of whole wheat.

Secondly, Dr. Frewen Moor (p. 531) asks what goods are made from flour in the milling of which it is permissible to extract germ—i.e., flour destined for manufacturing purposes. Such flour (known officially as "M" flour) is mainly used for self-raising flour or for making biscuits and confectionery goods. These goods are usually more alkaline than yeast-made bread, and in consequence of the *p*H being 7.0 or over the B_1 present is largely destroyed in the baking process. Hence the decision of the Ministry of Food to allow germ to be extracted in such cases, which represent only a small percentage of the total flour used.—I am, etc.,

Ealing, W.5. D. W. KENT-JONES.

SIR,—Some of us are not quite clear on this problem of flour and "extraction." It is a very important one indeed; can you not give us some unprejudiced information?

The term "extraction" is very popular; but is it correct? An 80% extraction means that 20% is taken out—*ex tractum.* What is implicated in altering the extraction from, say, 80 to 85%? If 5% more is left in, what is it—flour, bran, or what?

It is not clear why anything need be taken out, except to make extra profit on the bran, etc. But it is far less clear why millers should receive a special payment for doing so, for those who sell genuine wholemeal bread do not get the subsidy. One reason given for "extraction" being necessary is that the use of rollers requires it; but why not use a more modern and cheaper way of grinding, as by disintegrators?

Few statements take into account the proportion of flour which is imported as such, or the bran or vitamins that remain in the country of origin. Can we get data on this—the proportion of flour imported against what is grown here?

As one letter points out, it would be interesting to know for what purposes wheat is "destined" other than for human food. If for biscuits chiefly, then, surely, whatever arguments there are for leaving vitamins in bread hold more strongly for biscuits, for they are not raised to so high a temperature nor kept there so long. Also, they are much used by the working classes.

Incidentally, this problem illustrates how impossible it is to separate medicine from politics, unless one separates all that has to do with the health of the public from medicine; though so many other instances make it equally obvious, as tuberculosis, about which so many questions are asked in Parliament.—I am, etc.,

Kingston-on-Thames. W. F. COOPER.

SIR,—Lord Portsmouth stated in the House of Lords (*Hansard,* Feb. 28, 1945) that "Bemax is very largely the result of removing the most valuable constituents from the wheat berry before it is made into white bread." As a plain matter of fact this statement is incorrect.

Sir Ernest Graham-Little (April 14, p. 530) cites in defence of Lord Portsmouth only one real piece of evidence—namely, the answer given to him in the House of Commons on Sept. 8, 1942, to the effect that 99% of the germ "not retained in flour" (the quotation is verbatim from *Hansard*) was allocated for the use of proprietary products, either foods or medicines.

He overlooks the fact that just one month earlier Mr. Mabane, speaking on behalf of the Minister of Food had informed him that "no flour from which a proportion of the germ has been extracted is sold for any other than manufacturing purposes" (*Hansard,* Aug. 6, 1942). Nor was this an isolated reply. Similar information, variously phrased, was conveyed to Sir Ernest Graham-Little on June 9, June 30 July 16, July 23, 1942, and again in September, 1943.

It is quite clear that both Sir Ernest Graham-Little and Lord Portsmouth have fallen into the error of regarding Bemax a something abstracted from bread, whereas the truth is that th materials abstracted from bread—or flour used for bread making—are used exclusively for stock-feeding purposes and are permitted to be used for no other purpose.

It is thus clear that my assertion that not one flake or particle of Bemax is derived from flour either intended to be or actually used for bread-making is supported in the plainest and most unequivocal terms by the official record of the Proceedings of Parliament. It is also clear that the supply of raw materials for Bemax would be completely unaffected even if the rate of extraction were 100%. Suggestions to the contrary are inaccurate and merely confuse the main issue.

My comment on Dr. Frewen Moor's letter (p. 531) is brief. When Dr. Moor consults S.R.&O. No. 11 of 1943, to which I referred (now embodied in S.R.&O. No. 1, 1945, which I am sending him direct) he will find the information he seeks and will regret his accusation against me of contributing a half-truth to your pages.—I am, etc.,

H. C. H. GRAVES,
Chairman and Managing Director, Vitamins Limited.

Hammersmith, W.6.

U.C.H. and Sir William Gowers

SIR,—I have read with the greatest interest your leading article on Sir William Gowers (March 31, p. 452), and I appreciate every word of it, being one of the few survivors of a rapidly disappearing generation of University College men who still have a vivid recollection of Gowers, of his marvellous diagnostic skill, and the wide scope of his knowledge not only of the nervous system but of every branch of medicine, and of the manner in which he conveyed that knowledge to the students.

I entered University College in 1880 after having passed the preliminary scientific examination at the same time as Rose Bradford, Bayliss, and Raymond Johnson, who were all friends of mine. At that time University College had a very remarkable teaching staff, particularly the younger members, such as Marcus Beck and Godlee on the surgical side, and Victor Horsley, who rapidly established a world-wide reputation in surgery of the brain and spinal cord, and for research work on cerebral physiology, in some of which I was able to assist. Other outstanding men on the staff were Sydney Ringer, the physician, who was the greatest authority at that time on therapeutics, and known also for his research work on the influence of saline fluids on the development of tadpoles and the maintenance of regular pulsation of the excised heart of a rog for many months. (Of course Ringer's fluid is still as useful as ever.) There were also the physiologists, Burdon Sanderson, Sharpey-Schafer, and Ray Lankester, at that time the greatest living authority on comparative anatomy, who fterwards migrated to Oxford as professor.

Lister, the founder of antiseptic surgery, started his professional career at University College a good many years before then, but if it had not been for the conservative obstinacy of some of the older members of the staff would have developed his antiseptic system at U.C.H. instead of at Glasgow and Edinburgh. Lister's work was accepted with enthusiasm on the Continent of Europe, but in London, at the time my hospital training began, antiseptic surgery existed in only two hospitals —University College and King's. Sir Joseph Lister had come to King's College with his former house-surgeon, Watson Cheyne, and visited U.C.H. on several occasions and gave us lectures and demonstrations, which we greatly appreciated. U.C.H. was *facile princeps* of all the teaching hospitals in ngland, and the great majority of the honours and distinctions in the medical examinations of London University were won y its students.

Among the members of a brilliant staff Gowers was outstanding in versatility and diagnostic skill in all branches of inical medicine. His clinical lectures were profoundly interesting and original, and not only in the physiology of the nervous system, in which he was pre-eminent. He had a ungent humour, which was greatly appreciated by his audience. One of the best instances of his outstanding diagnostic skill, one which had, I feel sure, never been equalled before and of which Gowers himself was justifiably very proud, was as follows. The son of the chief hall porter at the hospital was seriously ill with paralytic symptoms, the details of which, if I ever knew them, I have forgotten. This was in 1881, when I was house-physician to Sydney Ringer, and I have a vivid recollection of the case, for I had the privilege of giving the anaesthetic (chloroform). Gowers's diagnosis was an abscess in the temporo-sphenoidal lobe of, I think, the left cerebral hemisphere. Gowers diagnosed its exact location, and pointed out to the surgeon—Rickman Godlee—the exact spot in which to introduce a trocar; as the stylet was withdrawn, pus was evacuated, and a small drainage tube was introduced. The patient made a rapid and complete recovery.—I am, etc.,

HERBERT H. BROWN.

Worthing.

Understating the Case

SIR,—The *Journal* of Feb. 10 has just reached me here and I have been interested to read the short symposium on Russian war surgery and your own editorial on that subject. While I consider it only right and proper that we should be able to read, in our journals, something of how our Russian colleagues are tackling the same problems of military surgery, I yet feel that you too, Sir, have fallen prey to what is a ubiquitous tendency in the popular lay press—the tendency to overrate all Russian results just *because* they are Russian, while at the same time neglecting to notice the even greater achievements of our own nation. It is a tendency not restricted to Russian affairs, but applies also to those of our other great ally. As a race we have a genius for understatement, perhaps especially when our own talents are the subject. This may have deceived Herr Ribbentrop, but it also gives our closest friends cause for surprise when they have occasion to see of what we are really capable.

To have staffed the medical services of a Force of the size of the Red Army 30 years after having had only 13 medical schools is certainly no small feat, but, bearing in mind the relative size of our own country, is no greater than what we have done. It is not only in the U.S.S.R. that "specialist treatment is provided . . . in forward zones," nor that "within a few miles of the front line there is segregation of cerebral, facio-maxillary, thoracic, and orthopaedic cases." And yet the editor of that daily paper which delights in regaling its Saturday morning readers with extracts from the latest *British Medical Journal* might have been forgiven if, after reading your leading article, he had penned a demand for mobile neurosurgical units in the British Army! I am not suggesting that you should cater for such a reader, but even a British civilian doctor might have wondered whether, perhaps, the Russians had "got something there." The Russian medical services have never had to evacuate, on D-day itself, casualties from a huge assault force across the English Channel, nor did our medical services break down during the dash across Belgium. I have not seen any Russian surgery, but experience in both European theatres has shown me no results that I have felt could be improved upon by either the Russian or American Army Medical Corps. This we have done using only the advice and suggestions of our consulting surgeons without any recourse to "central dictation of technique. . . ." Indeed, there is a friendly rivalry in surgical results between, for instance, B.L.A. and C.M.F., and it is difficult to imagine a British surgeon applying skeletal traction to a humerus merely because he was ordered to do so from London.

I hope I shall not be thought to be "making a mountain out of a molehill" and occupying valuable printing space, but I should not like to see our *Journal* taking the all-too-popular line of writing up the occasionally more spectacular work of others at the expense of our own, sometimes less colourful, achievements.—I am, etc.,

DONALD V. BATEMAN,
Capt., R.A.M.C.

C.M.F.

Histological Specimens Wanted

SIR,—Two months ago this medical school suffered severe damage. Among other very serious losses almost the entire stock of histological material, both blocks and pots of specimens, has been destroyed. We should be most grateful for any human material suitable for the second M.B., B.S. histology course. The material, as fresh as possible, should be put into 7% formol-saline. We will gladly refund any expenses incurred and also return receptacles: we can collect material in London on receipt of a postcard sent to me at the London (Royal Free Hospital) School of Medicine for Women, 8, Hunter Street, W.C.1.—I am, etc.,

EVELYN E. HEWER.

Final M.B. of London University

SIR,—As a member of H.M. Forces I would like to contribute an opinion, not yet voiced, on the new London M.B. regulation. I suspect and hope that the reason the new regulation applies to those beginning finals is that in further carving up the examination the standard of the whole will fall unless the pass mark of each part is correspondingly raised.

For the many in the Forces and elsewhere who struggled with this respected monster in its old form, of which I am one, many more than of the kin of Surg. Lieut. Trevor Davies (April 21, p. 571), it would be unfair if in its now more segmented form the M.B. should fall in standard.—I am, etc.,

JOHN C. L. ADAMS,
Surg. Lieut., R.N.V.R.

Revised Syllabuses of the General Nursing Council

SIR,—I think many must have read with considerable apprehension the revised syllabuses for both the preliminary and final State examinations, especially as on the front page appears the statement "As Approved by the General Nursing Council for England and Wales." I can hardly believe that they are approved by either the medical and nursing professions or the hospitals who will have to administer them.

In my opinion many of the subjects have nothing whatever to do with the training of a practical nurse; for instance, on page 7 of the subjects for the final State examination appears a paragraph, "Structural defects of houses unfavourable to good domestic management." It would be interesting to know exactly what this means. In both syllabuses appears the word "lighting," but nowhere has any provision been made for some instruction in electricity. Although many and varied electrical appliances are used in hospitals, few, if any, student nurses know the difference between alternating and direct current, why an earth is necessary, the meaning of voltage, nor, as a rule, is any instruction given in the proper use of electrical heating pads, surgical diathermy machines, electric cradles, etc. Surely some simple instruction could be given on these matters, and on the simple precautions which must be taken when using electrical appliances. Unfortunately, there have of late been several accidents in hospitals caused entirely by this lack of knowledge.

In conclusion, I feel that the time has now come when a firm stand should be made against the arbitrary manner in which the General Nursing Council treats both the nursing profession and the hospitals. Almost daily in the press there are paragraphs complaining of the shortage of nurses, but instead of making matters easier the General Nursing Council seems intent on making it more difficult for a girl to train as a nurse.—I am, etc.,

Royal Hospital, Richmond, Surrey.
AUCKLAND.

The Services

Capts. J. P. J. Burns, W. F. Caldwell, J. B. Jayne, J. W. L. Kemp, and L. M. Reid, R.A.M.C., and Capt. C. L. Kashyap, I.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in Italy.

The following appointments, awards, and mentions have been announced in recognition of gallant and distinguished services in Burma:

M.B.E. (Military Division).—Major (Temp.) J. J. Elbert and Capt. M. M. Campbell, R.A.M.C.

M.C.—Capts. J. S. I'A. Chesshire, R. A. B. Kinloch (attached Indian Army), O. P. Llewellyn, and T. C. Thorne, R.A.M.C.; Capt. G. V. Faulkner, I.M.S.

Mentioned in Dispatches.—Major P. Baker; Majors (Temp.) G. A. S. Akeroyd, J. Donaldson, J. W. N. Duerden, C. R. Houghton, M.B.E., and J. S. McCrae; Capts. O. C. Colt, D. W. Evans, P. Firstenberg, H. A. Gibb, L. C. L. Gonet, E. J. Harrison, D. C. Langwell, F. Luckett, J. R. McGregor, P. M. M. Pritchard, T. B. L. Roberts (attached 9th Gurka Rifles), and J. R. D. Williams; Capt. (Temp.) T. A. Taylor, R.A.M.C. Major (Temp.) E. A. Tarleton and Capt. K. L. Chitwal, I.M.S. Capt. E. P. O'Neill, I.A.M.C.

Obituary

GILBERT ORME, M.B.

The death of Dr. Gilbert Edward Orme on April 7 removes one of the best known as well as one of the most popular and best beloved of West End London practitioners —one who had more friends and fewer enemies than almost any man in the medical profession. Educated at Caius College, Cambridge, and St. George's Hospital, he became M.R.C.S., L.R.C.P. in 1899 and M.B. in 1901; at both places he was prominent as an oarsman and a footballer, and rowed in many winning crews in first-class company. After house appointments at his own hospital and at the Victoria Hospital for Children, he went into practice for some years at Clitheroe, in Lancashire, and was president of the Lancs and Cheshire Branch of the B.M.A. After moving to London a good many years ago he occupied a similar position in the Westminster and Holborn Division, and in addition did good service as member of council of the King's Hospital Fund, the Queen's Institute for District Nursing, the League of Mercy, and on the Interdepartmental Committee on Nursing Services. Gilbert Orme, who was born and brought up in Australia, was a man of fine physique, courteous manners, pleasing voice, and good address generally; his success in London practice was as assured as it had been in Lancashire, for in addition to these advantages he had also a thorough knowledge of his profession and a conscientious sense of duty. He travelled to Melbourne with the B.M.A. party for the Annual Meeting there in 1935, and as usual, made firm friends of all who were privileged to mee him.

Dr. ANDREW J. SHINNIE, medical officer of health, City o Westminster, and Dr. J. A. STRUTHERS, medical officer of health Borough of Holborn, send the following appreciation:

We feel we should like to pay a special tribute to the lat Dr. Gilbert Orme. Shortly before the war, as the recently electe chairman of the Westminster and Holborn Division it naturally fe to him to be appointed to the chair of the Local Medical War Committee. We are not likely to forget the immense amount of wor put in by him and the hon. secretary, Dr. Wood Smith (later D Maxwell Chance) in compiling a census of the practitioners in th Division. The needs of the war had to be assessed and likewis the claims of practice, while the selection and nomination of thos best fitted for the work then looming ahead proceeded. This process might well have been fraught with some heartburning had i not been pursued with so much good will and understanding. A a result when war came all the medical staffing for Civil Defenc services which came under our control was complete and ready fc action.

Many problems of varying magnitude came before the local committee. Still many more were dealt with by him by that sur conciliatory touch which made contending parties feel they had ha a square deal. He was unsparing of himself in visiting by day an by night depots and posts in the area where he himself was a par time volunteer and played an active part in dealing with casualtie When the medical service in public air-raid shelters was institute his advice again proved invaluable, and he himself shared in th service. It is no exaggeration to say that largely by his efforts sense of common responsibility and co-operation between the docto practising in the Division and the health services of the two loc authorities has been fostered which it is hoped will grow an prosper to the future benefit of all concerned. Tolerance and goc temper always characterized his conduct in the chair, and we sha miss his genial and urbane presence. There is no doubt that h spent himself in war service and denied himself the leisure to whi a long and honourable career in medical practice had fully entitl him.

R. LAWFORD KNAGGS, M.CH., F.R.C.S.

Mr. Robert Lawford Knaggs, who died in retirement at For Park, Newton Abbot, Devon, on April 16, was one of the be known surgeons in Leeds until he left that city about 25 yea ago. He was consulting surgeon to the General Infirmary a from 1910 to 1919 professor of surgery in the University Leeds.

He began the study of medicine at Cambridge and continu it at Guy's Hospital, qualifying in 1883, and taking the F.R.C a year later. At Cambridge he graduated M.B., B.Ch. in 18 M.D. in 1888, and M.Ch. in 1890. After house appointme at Guy's he settled in surgical practice at Leeds and was appointed to the staff of the General Infirmary. Lawford Knaggs was a member of the Court of Examiners of the Royal College of Surgeons of England for ten years (1911–21), a Hunterian professor in 1923–5, and in 1930 received the rare distinction of the Honorary Gold Medal of the College at the hands of his Leeds contemporary Lord Moynihan, then President, in recognition of his great services to the Hunterian Museum. Among many labours of love at Lincoln's Inn Fields he catalogued and revised the Strangeways collection of specimens illustrating arthritis.

Lawford Knaggs published in 1926 a book, *Inflammatory and Toxic Diseases of Bone,* which reflected his experience both as a practical surgeon and as one who had made an intimate study of the subject from the pathological side. This country has a wealth of specimens in its museums exemplifying various diseases of bone, and to illustrate his theme he made use of that material not only from the extensive collection in his own university of Leeds, but also from the abundant material in the Museum of the Royal College of Surgeons and in the London and Provincial medical schools. The writing of this book was undertaken as a congenial task after Knaggs had retired from active surgical duties. He kept the clinical aspect in the foreground and duly emphasized the practical bearing of the pathology of the subject.

G. T. BIRDWOOD, M.D.

Gordon Travers Birdwood died suddenly at Deal on April 14 at the age of 78; he had practised there for 25 years after his retirement from the Indian Medical Service with the rank of lieut.-colonel. His father was H. M. Birdwood, a distinguished member of the Indian Civil Service, and he was educated at Clifton College, at Peterhouse, Cambridge, and at Guy's Hospital. He qualified in 1892, took his M.A. and M.D. degrees at Cambridge in 1895, and the D.P.H. in 1896. Four years earlier he had gained second place in the entrance to the I.M.S., and he served with distinction in India in the Abor Expedition and in the Waziristan and Chitral campaigns. As principal of the Agra Medical School 1903–10 he completely remodelled the curriculum and enlarged the buildings. His next appointment, which he held for eight years, was to the new chair of midwifery at Lucknow Medical College, and he organized the teaching on the model of the Rotunda Hospital at Dublin. He also had charge of the Babrampur Hospital, and was responsible for many improvements there. He was made a Fellow of Allahabad University and a member of the Child Welfare Committee of the Province. While serving in India Birdwood wrote two books, *Clinical Methods in Tropical Diseases* and *Practical Bazaar Medicines,* which have been much in demand.

On his retirement in 1920 from the I.M.S. he began practice in Deal and Walmer; he was at once appointed surgeon to the newly built Deal and District War Memorial Hospital and until 1937 was its keen and active senior surgeon. He became president of the East Kent Association of Surgeons in 1934 and was for ten years medical officer of the Deal Child Welfare Centre, a work to which he devoted himself whole-heartedly. He gave much attention to the Deal Hospital and its development, inaugurating in 1935 an ophthalmic department, and for seven years was a vigorous member of the committee of management. He had joined the B.M.A. in 1896, was honorary secretary of the Dover and Folkestone Division 1926–9, chairman of the Dover Division 1929–33, and from 1938 till his death emergency officer for East Kent.

Birdwood took a prominent part in the affairs of the town of Deal, where his elder brother, Field-Marshal Lord Birdwood, holds the ancient office of Captain of Deal Castle. He served for six years on the Borough Council, was twice deputy mayor, and had been president of the local Chamber of Trade.

The following well-known medical men have died abroad: Dr. **David Wolfstein**, professor of psychiatry in the University of Cincinnati, aged 86; Dr. **Louis B. Wilson**, formerly professor of pathology at Minnesota University, aged 70; and Dr. **Gustav Aschaffenburg**, for 30 years professor of psychiatry at Cologne, who died at the age of 78 at Baltimore, where he had been living in exile since 1938.

Universities and Colleges

UNIVERSITY OF OXFORD

An election of two members of the Board of the Faculty of Medicine will be held on June 6. The members elected will come into office on the first day of Michaelmas Term, 1945, and will hold office, the senior for two years and the junior for one year, from that day.

The general medical electorate consists of all Oxford graduates in medicine who are members of Convocation. The Board of the Faculty of Medicine includes two members elected by the general medical electorate who must be members of that body and of whom one at least must be a person engaged in teaching one or more of the clinical subjects of the Faculty.

Nominations of duly qualified candidates for election will be received by the Secretary of Faculties at the University Registry up to 10 a.m. on May 16. Each nomination must be signed by six members of the general medical electorate, and no candidate will be eligible whose nomination has not been received by that date.

UNIVERSITY OF CAMBRIDGE

The Linacre Lecture will be delivered by Prof. E. D. Adrian, O.M., M.D., F.R.S., on Monday, May 7, at 5 p.m., in the lecture-room of the Physiological Laboratory. The title of the lecture is "The Pulsation of the Brain."

The Professor of Anatomy gives notice that applications for the Marmaduke Shield Scholarship in human anatomy are to be sent to the Registrary on or before May 20. The persons eligible are undergraduates of not more than three years' standing from matriculation, and B.A.s of not more than four years' standing from matriculation, who have completed the First M.B. Examination, are qualified in anatomy and in physiology to proceed to the Final M.B., and have also obtained honours in Part I of the Natural Sciences Tripos with anatomy as one of their subjects. Women also are eligible.

Candidates for the Michael Foster Studentship in physiology should send their applications, with a statement of the course of research they propose to undertake, to Prof. Adrian, Physiological Laboratory, on or before June 30.

During the month of March the title of the degree of M.D. was conferred by diploma on Mrs. M. H. D. Gunther, of Newnham College.

UNIVERSITY OF EDINBURGH

At the last meeting of the University Court intimation was made of the receipt of a sum of £3,024 subscribed by patients and other friends of the late Dr. Andrew Graham Ritchie, F.R.C.P.Ed. The sum is to commemorate the high esteem and affection in which he was for many years held by all sections of the community in Edinburgh, by founding a bursary to be awarded annually to an undergraduate in the Faculty of Medicine. The Court gratefully accepted the donation.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

Election of Fellows

At a quarterly Comitia of the College held on April 26, with the President, Lord Moran, in the chair, the following were elected Fellows:

S. P. Bedson, M.D., F.R.S. (London); Major-Gen. S. R. Burston, C.B., C.B.E., D.S.O., F.R.C.P.Ed., F.R.A.C.P. (Melbourne, Australia); Sir Ernest Rock Carling, M.B., F.R.C.S. (London); Brig.-Gen. P. R. Hawley, M.D. (U.S.A.); C. H. Whittle, M.D. (Cambridge); S. H. Cookson, M.D. (Bournemouth); J. A. Birrell, M.D. (Bristol); W. A. Robb, M.D. (Exeter); George Fletcher, M.D. (Manchester); C. S. Hallpike, M.B., F.R.C.S. (London); Maurice Mitman, M.D. (Dartford); Arthur Burrows, M.D. (London); R. G. Cochrane, M.D. (Madras); G. W. Bamber, M.D. (London); Ewen Downie, M.D., F.R.A.C.P. (Melbourne, Australia); A. Margaret C. Macpherson, M.D. (London); A. G. Ogilvie, M.D. (Newcastle-upon-Tyne); Philip Ellman, M.D. (London); C. Allan Birch, M.D. (London); Benjamin Barling, M.D. (London); Eliot T. O. Slater, M.D. (Oxford); T. E. Gumpert, M.B. (Sheffield); W. C. Smallwood, M.B. (Birmingham); H. C. Trowell, M.D. (Uganda); C. H. Rogerson, M.D. (Stoke-on-Trent); Stanley Alstead, M.D. (Glasgow); P. R. Evans, M.D. (London); L. J. Davis, M.D. (Edinburgh); Mahmoud Erfan (Cairo); W. H. Kauntze, C.M.G., M.B.E., M.D. (London); W. R. M. Drew, O.B.E., M.B. (London); S. A. Henry, M.D. (London).

Dr. L. G. Parsons and Dr. Donald Paterson were appointed representatives of the College to attend the Conference of the National Association of Maternity and Child Welfare Centres. Lord Moran was elected a representative of the College on the Governing Body of the British Postgraduate Medical School and Sir Arthur Hall a representative on the Board of Governors of Sheffield University. Dr. G. E. S. Ward was appointed an External

Examiner in Medicine for the Fellowship examination of the Faculty of Radiologists. Members were nominated to serve on a dermatology committee. Reports were received from the Consultant Services Committee and from the Paediatric Committee.

New Members

The following candidates, having satisfied the Censors' Board, were elected Members:

T. J. Agius-Ferrante, M.D., Patience E. Barclay, M.B., O. W. Chapman, M.B., J. D. Craig, M.B., Fl. Lieut., R.A.F.V.R., Joyce A. Davies, M.B., Capt., R.A.M.C., H. J. W. Fisher, M.B., G. Garmany, M.B., Surg. Lieut.-Cdr., R.N.V.R., C. C. Houghton, M.B., A. H. Isaacson, M.B., A. E. Jones, M.B., Capt., R.A.M.C., H. B. Kelly, M.B., Monica K. McAllen, M.B., O. Magidson, M.D., G. R. B. Newns, M.B., K. N. V. Palmer, M.B., D. A. R. Pond, M.B., Cynthia M. Redhead, M.B., R. V. Stone, M.B., J. M. Stowers, M.B., R. McL. Todd, M.B.

Licences and Diplomas

Licences to practise were conferred upon the following 139 candidates (including 29 women) who had passed the Final Examination in Medicine, Surgery, and Midwifery of the Conjoint Board and who have complied with the necessary by-laws:

E. M. Allen, C. F. Allfrey, E. A. J. Alment, W. McC. Anderson, E. T. Anderton, R. J. Aspinal, D. J. Atherton, C. M. Attwood, D. A. Bailey, R. W. Barr-Brown, H. F. McG. Bassett, A. J. T. Bateson, A. M. H. Bennett, J. P. M. Bensted, A. Bernstein, Diana M. Beyts, M. Binnie, G. L. Bourne, C. W. Bowen, J. H. Boydell, Margaret Bywaters, F. E. V. Cant, Mary N. A. Carlile, H. F. Chapman, Irene M. S. Chappel, H. C. Churchill-Davidson, I. F. J. Churchill-Davidson, Iris B. F. Collinson, J. S. Conway, J. N. C. Cooke, S. Copp, Vera M. Dalley, H. T. Davenport, D. G. Davidson, D. F. Davies, J. A. Dew, A. McK. Dorey, E. L. Dutta, J. C. Edwards, F. T. Falkner, Eve G. Field, S. G. A. Forsyth, S. Galeswski, G. G. Garlick, B. Geoghegan, B. George, W. P. D. Green, Brigit M. Griffiths, Ruth A. Haes, A. E. Hall, N. Harrison, R. A. C. Hart, Joan Haythorne, N. M. O'C. Hewett, Ruth Jackson, D. D. E. Jewitt, P. H. A. Jonason, C. J. M. T. Jones, E. R. Jones, R. S. Jones, M. C. Joseph, C. R. Kirkpatrick, M. Kirwan, M. R. Kohli, Jean V. Lang, R. McK. Laslett, Pamela Laws, A. O. Laymond, Constance G. Lee, P. G. Leese, J. A. Litchfield, A. H. M. Littlewood, Jessie B. Macaulay, H. B. Maliphant, I. G. Manning, P. M. C. Mark, Margaret M. Mason, G. G. Mathew, J. C. Matthews, J. B. Metcalfe, J. N. Micklem, Mary H. Moller, R. E. Moore, J. A. B. Mounsey, Margaret C. Myddelton, R. F. Naunton, Moragh J. Noakes, C. Ormston, Jannette D. Ap-H. Owen, T. E. Owen, Frances I. Panton, Cynthia M. Parrott, R. F. Payne, Noel J. Pease, Thelma M. Phelps, B. Ll. C. Phillips, J. R. H. Pinkerton, J. L. Pring, C. W. A. Pullan, D. A. Pyke, R. J. Rabett, R. Randell, D. Richter, E. G. G. Roberts, R. Ll. B. Roberts, D. J. Rudman, P. I. Rutherford, A. H. B. Rydon, Betty J. Schofield, J. C. Seymour, D. S. Sharpe, Joan M. Sheehan, G. W. Shepherd, N. I. A. Shohet, Betty E. Shortland, P. H. S. Silver, R. B. Sloane, J. Stevenson, H. J. C. Swan, Margaret M. Sweeney, M. T. Sweetnam, J. C. Talbot, B. O. T. Taylor, W. D. G. Tellam, J. M. Thomas, Mary E. I. Upsdell, D. F. van Zwanenberg, C. C. Vidot, O. L. Wade, R. V. Walley, E. McP. Watts, W. Waugh, N. T. Welford, P. W. Wells D. Whitehouse, M. Wigram, D. J. K. Wilkie, G. V. S. Wright, F. J. Yeardsley

Diplomas in Ophthalmic Medicine and Surgery were granted, jointly with the Royal College of Surgeons of England, to the 14 persons whose names were published in the *Journal* of March 31 (p. 460), as were the names of the 14 persons who were granted Diplomas in Medical Radiology. Diplomas in Child Health were granted to the 18 persons whose names were published in the report of the meeting of the Royal College of Surgeons of England in the *Journal* of April 21 (p. 573).

A Diploma in Medical Radiotherapy was granted to L. M. Shorvon and a Diploma in Medical Radiodiagnosis to J. A. Ireland, both jointly with the Royal College of Surgeons of England.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

The following lectures will be delivered at the College (Lincoln's Inn Fields, W.C.) at 4 p.m. each day: May 4, Hunterian Lecture by Prof. A. S. Aldis, Injuries of the Pancreas and their Surgical Treatment. May 7, Arris and Gale Lecture by Prof. F. Davies, Early Development of the Human Embryo. May 9, Arris and Gale Lecture by Dr. D. V. Davies, Synovial Membrane and the Synovial Fluid of Joints. May 10, Hunterian Lecture by Prof. R. Watson-Jones, Limb and Spine Injuries due to Flying Accidents. May 11, Arris and Gale Lecture by Mr. Judson T. Chesterman, Some Alterations of the Neuromuscular Balance of the Intestine and their Clinical Significance. May 25, Prof. Arnold Sorsby, Blindness in Great Britain: the Structure of the Blind Population and the Causes of Blindness. May 29, Prof. Sorsby, Penicillin and Gramicidin S in Ophthalmology. May 31, Prof. James Patrick, A Study of Supination and Pronation, with Special Reference to the Treatment of Forearm Fractures. The lectures are open to medical practitioners and advanced students.

CONJOINT BOARD IN SCOTLAND

The following candidates, having passed the requisite examinations, have been admitted L.R.C.P.Ed., L.R.C.S.Ed., L.R.F.P.&S.Glas.:

R. J. G. Aitken, O. E. A. Antia-Obong, H. Baytch, I. J. Bernstein, A. E. R. Campbell, I. G. Campbell, J. D. C. Campbell, H. Camrass, B. Chromow, D. Craig, G. C. Fletcher, A. Gerber, Adrien A. Holder, A. Ingram, J. M. Leith, T. Leven, W. E. Lotfy, Alison M. Matheson, A. A. A. Mazen, J. M. Moore, R. E. Morgan, M. N. Padayachee, F. L. Paterson, T. W. Poole, W. E. Robinson, J. C. Rohan, A. L. Rose, D. H. Rosenberg, I. J. Selikoff, H. J. Shapiro, P. Shenkin, M. Silver, D. H. Sinclair, P. Steinlauf, J. Waddell, R. R. Wilson, J. Wotherspoon, M. Zimnowitz.

The following graduates of recognized foreign universities were also admitted licentiates: J. Weiss and W. C. S. von Reybekiel.

Medical Notes in Parliament

National Health Service

Dr. SUMMERSKILL on April 26 said the answers given to her by Ministers on the White Paper on health services had been so unsatisfactory that she felt she must raise the matter again. Last year the House had very carefully debated the White Paper. If it was intended to change the fundamental principles of that White Paper she suggested that the Government should produce another one and that the House should discuss it. Some months after the introduction of the White Paper rumours asserted that the Minister of Health was having further talks with interested bodies which had already discussed the subject. Finally the rumours were substantiated, and a document, which was circulated to over 70,000 doctors in this country, was published. The document was marked "Not for publication." She felt it was so marked because it could not stand the glare of publicity. But it was no longer secret. Newspapers, medical publications, and leaflets of all kinds had given details and had been distributed among doctors and the public.

In the proposals which the Minister had put to the B.M.A. there was a complete change in the attitude of the Government towards the new health services. A progressive medical opinion in this country had pictured the health centres as places where doctors would co-operate rather than compete, and where the preventive approach to medicine would be emphasized. In the new proposals which Mr. Willink had put to the B.M.A. it was suggested that there should be a few experimental health centres, but that local authorities should have no clinical supervision; that doctors would come and work there but their work would not be supervised; and that the only contract between the doctor and the local authority would be that of landlord and tenant. The proposal was that the doctor could conduct his private practice in the health centre as it was conducted outside. She and her friends had looked forward to the day when doctors would be employed in the health centres on a full salaried basis. That had all gone.

Mr. WILLINK intervened to say that Dr. Summerskill had given the impression that she referred to a document issued by the Ministry of Health. If she was referring to a document she had received from the B.M.A. as a member of that Association she should make this clear.

Dr. SUMMERSKILL said the document had been published by the B.M.A. and she was going to quote from it.

Mr. WILLINK declared that no document had been published by the B.M.A. One had been sent to members and marked "Not for publication." He gathered this was the document to which Dr. Summerskill referred.

Dr. SUMMERSKILL said the document had been mentioned in the House on many occasions and questions had been put about it. It had been circulated to doctors and its contents were no longer secret. Lay persons throughout the country had seen it, and a leaflet had been issued by another organization. She asserted that this document contained proposals made by Mr. Willink which were to be put to a representative meeting of doctors in the week beginning April 29, and that the time might come to reveal this matter which concerned every man, woman, and child. She had asserted in questions that the Minister had made these proposals to the B.M.A. This he had denied time after time. She claimed that she had shown that the change in the health services was a complete change in principle. The full-time salaried medical service which the House approved last year was to be dropped. There was a suggestion of some part-time service. Otherwise doctors were to be paid on a *per caput* basis. The Minister was proposing to the B.M.A. an extension of the panel system. The Minister in that House had thrown doubts on her veracity and the House must know whether he or she had departed from the truth. She wished to expose a piece of calculated dishonesty. Dr. Summerskill then cited questions which she had put to the Minister and answers given to her, to Mr. Lipson, and to Mr. A. Bevan. She read what she said was the first paragraph of the document, which ended: "They are proposals which the Minister will be willing to put to his colleagues as soon as he knows whether they commend themselves to the medical profession." If Mr. Willink denied again that these were his proposals and that the B.M.A. had any mandate on May 3 when the doctors would meet to consider them he should tell the House now.

Mr. LINSTEAD said the mystery which the House had anticipated had not been disclosed. He put a completely differen interpretation upon the statements made by the Minister from that which had been given them by Dr. Summerskill. He thought Mr. Willink had said: " I have had discussions with the B.M.A. which cannot commit my colleagues in the Government and cannot commit the members of the B.M.A. Let the Negotiating Committee talk to the doctors and see if they agree. If they do I will talk to my colleagues in the Government and see if I can persuade them to agree. Until I have talked with my colleagues I cannot be certain that these proposals will commend themselves to the Government." The debate in the House on March 17, 1944, had shown that the proposals came under considerable criticism. Members on the Conservative side of the House regarded the civil-servant doctor as one of the big flaws in the original proposal. They did not wish to see the doctor in the Civil Service or the patient in the " pigeonhole." The House was in no way committed to the White Paper by the resolution which it had passed. He added that a year was a long time for consideration of such proposals by the B.M.A., and when that body had finished its discussions next week members ought to be put in full possession of the fact so that the House could turn its attention to the final form which the health service was to take.

Mr. STOREY asserted that Dr. Summerskill had put a mischievous view before the House. Mr. Willink had taken a common-sense course. He discussed the proposals with the three bodies likely to offer constructive criticism—the B.M.A., the British Hospitals Association, and the local authorities. Mr. Storey said he himself had seen certain of the alternative proposals which had been put before one of these bodies. In his opinion they went a long way to improve the White Paper proposals.

Mr. MESSER asked whether Mr. Storey agreed that the B.M.A. should have done what the British Hospitals Association and the local authorities had done and not made public the negotiations.

The Minister Replies

Mr. WILLINK said he was not surprised at the violence of Dr. Summerskill's language nor that she appeared to show ignorance of the steps to be taken in working out a service of this comprehensive nature. What surprised him was her ignorance of the White Paper itself. The proposal of a comprehensive health service had been initiated by the Government in a speech by Sir John Anderson in Feb., 1943. In the following twelve months there were discussions which the White Paper did not purport to sum up. Nor did the White Paper purport to reflect any agreement or represent any view reached in those discussions, which would be inconsistent with the terms on which the discussions were undertaken. Parliament had understood that, as soon as the White Paper was published and debated, detailed discussions would follow. The White Paper said on page 77 that it would serve as a focus for detailed discussion. That discussion had since been going on and was going on still. Mr. Willink added that no member of the medical profession had disclosed to him the document to which Dr. Summerskill had referred. Was it wrong to obtain general agreement to a scheme? Was Parliament or the public being treated unfairly? The Government had been greatly helped by the discussion of the White Paper by the Commons and the Lords. They were now discussing it more widely. They had reached no finality. The proper course was to come to a stage where the discussion had gone far enough and the Government could consider where those discussions had led them. Legislation would then be introduced. The whole medical profession, those interested in voluntary hospitals, and those interested in the work of local authorities could not discuss these matters with Mr. Johnston and himself. They sent their spokesmen, and these spokesmen desired to report on the progress of the negotiations. In four sections of interested opinion—the local authorities, the voluntary hospitals, the medical profession, and the dental profession—this was going on at the moment. But there were no proposals. Mr. Johnston and he had not reached a stage when they could put the whole thing together to place it before their colleagues.

Dr. SUMMERSKILL asked whether the doctors should not have been called to the meeting of the following week believing that Mr. Willink was willing to put these proposals [in the document] if they commended themselves to the medical profession.

Mr. WILLINK said he could take no responsibility for the contents of the document, which he had not seen, which was not intended for his eyes, and had not been published. It was a document which was perfectly proper to have come into existence, but its publication was unfortunate and regrettable. That publication had nothing to do with the negotiating body of the medical profession. Nothing similar had occurred in the other bodies with whom he had discussed these matters.

Dr. MORGAN said the right thing had been done.

The debate then concluded.

Committee on Medical and Nutritional Problems

Replying on April 17 to Sir E. GRAHAM-LITTLE, Mr. Mabane said the following were at present members of the standing committee of the Ministry of Health on Medical and Nutritional Problems. This committee was set up in the early part of 1941 and had since that date been consulted by the Ministry of Food on many questions connected with food and health.

Ministry of Health.—Sir Wilson Jameson (Chairman), Mr. P. N. R. Butcher, Dr. W. A. Lethem, Dr. H. E. Magee, and Dr. D. M. Taylor.

Ministry of Food.—Sir Jack Drummond and Lord Horder.

Board of Education.—Dr. J. Alison Glover.

Medical Research Council.—Sir Edward Mellanby, Prof. S. J. Cowell, and Dr. B. S. Platt.

Department of Health for Scotland.—Dr. A. Davidson.

Ministry of Agriculture and Fisheries.—Mr. R. G. R. Wall.

Department of Scientific and Industrial Research.—Dr. C. S. Hanes.

Ministry of Supply.—Dr. A. J. Amor.

Ministry of Fuel and Power.—Dr. S. W. Fisher.

Adult Population of Great Britain

In reply to Sir E. Graham-Little, Mr. WILLINK stated that the total adult population of England and Wales at June 30, 1944, the date of last ascertainment, inclusive of the armed Forces of the country temporarily abroad and exclusive of the armed Forces of Dominions, Colonies, and foreign countries temporarily present in the country, is estimated at approximately 30,104,000. The corresponding figure for Scotland is approximately 3,490,000. The adult civilian population in Northern Ireland at that date is estimated at approximately 820,000.

Medical News

A memorial service for Sir Hubert Bond will be held in the chapel at Long Grove Hospital, Epsom, to-day (Saturday, May 5) at 12 noon.

The Czechoslovak Medical Association and the Association of Austrian Doctors in Great Britain are holding a medical film show to-morrow (Sunday, May 6), at 3 p.m., in the Hastings Hall, B.M.A. House, Tavistock Square, W.C. Programme: (1) Surgery in Chest Diseases, (2) A Rare Operation, (3) Red Army Hospital. Guests will be welcome.

On Tuesday, May 8, at 2.30 p.m., at the Royal Society of Tropical Medicine and Hygiene, 26, Portland Place, W., Mr. Eardley Holland, F.R.C.O.G., will give a Chadwick Lecture on the importance of a maternity service in the life of the nation. Admission is free; tickets are not required.

A paper on " Infantile Paralysis " will be read by Dr. F. M. R. Walshe before the Royal Society of Arts (John Adam Street, Adelphi, W.C.), on Wednesday, May 9, at 1.45 p.m.

A general meeting of the Tuberculosis Association will be held at 26, Portland Place, W., on Friday, May 11, at 3.30 p.m., when there will be a discussion on " Pregnancy and Tuberculosis," to be opened by Dr. M. H. Logg and Miss Josephine Barnes, F.R.C.S. The date of this meeting has been changed from May 18.

A week-end industrial course, for industrial medical officers of health, will be held at the London School of Hygiene and Tropical Medicine (Keppel Street, W.C.) on Saturday and Sunday, May 12 and 13. The programme is as follows: May 12, discussion on " The Value of Early Diagnosis," with contributions, at 2 p.m. by Dr. A. J. Amor on " The Clinical Approach to Industrial Medicine," and at 3.30 p.m. on " The Early Investigation of the Industrial Environment " by Mr. R. F. Milton. On May 13, at 10.30 a.m., Dr. Donald Hunter will speak on " The Early Diagnosis of Industrial Diseases "; at 11.45 a.m., Prof. Ida Mann, on " The Early Diagnosis of Diseases and Injuries of the Eye "; and at 2.15 p.m., Lieut.-Col. G. R. Hargreaves will discuss " Personnel Selection and its Relationship to Mental Health." The fee of £1 1s. for the course and 2s. 6d. if lunch is required on the Sunday should be sent to the secretary, London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1, by May 7.

A meeting of the South Wales Branch of the Institute of Physics will be held on Saturday, May 12, at 2.30 p.m. in the Physics Department of the University College, Cathays Park, Cardiff, when Prof. W. V. Mayneord will lecture on " The Use of Infra-red Radiation in Medicine.". The meeting will be open to visitors.

Dr. H. D. Kay, F.R.S., will give an address on " The Secretion of Milk " before the Royal Institution (21, Albemarle Street, W.) on Friday, May 18, at 5 p.m.

The Industrial Welfare Society (14, Hobart Place, Westminster, S.W.1) has issued a pamphlet, *Plan for Reinstatement*, at the price of 1s. post free. It has been planned to cover a number of points in the Government's publication *Release and Resettlement*, which is issued to Service men and women to inform them of the official arrangements being made for their resettlement after discharge. An appendix offers suggestions for a " Reinstatement Record Form "—indispensable for all firms' reinstatement schemes.

A meeting of St. Marylebone practitioners, arranged by the St. Marylebone Medical Committee under the chairmanship of Dr. Geoffrey Marshall, will be held at the Royal Society of Tropical Medicine and Hygiene, 26, Portland Place, W., on Wednesday, May 16, at 8.30 p.m., to discuss important matters arising out of the Special Representative Meeting of the B.M.A. and to make recommendations.

Ninety-five English medical students have gone to Europe to help in the relief of starvation. Fifty Scottish students are standing by for the same purpose.

Major-Gen. Sir Ernest Cowell was last week admitted to the freedom of the borough of Croydon, being the first medical man among the nineteen upon whom this honour has been conferred.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* measles notifications fell during the week by 22,574 cases, and those for scarlet fever by 128; whooping-cough was more prevalent by 191 cases, and dysentery by 157.

Lancashire had 36 fewer cases of scarlet fever than last week. The largest local variations in the returns of diphtheria were increases of 12 in Staffordshire and 10 in Warwickshire, and a fall of 14 in Cheshire. Two local outbreaks of diphtheria, one in the village of Abergynolwyn, Merionethshire, and the other in Northumberland, Amble U.D., persist, and the local authorities are taking measures in an attempt to control the outbreaks. A small rise in whooping-cough occurred in all regions except the south-western. The notifications of measles fell by over 100 in fifteen counties, notifications being lower than last week by the following numbers: Yorks West Riding 520, Leicestershire 318, Middlesex 206. A rise of 170 occurred in Monmouthshire, of 133 in Kent, and of 111 in Glamorganshire.

Notifications of dysentery were high. In Middlesex cases rose from 4 to 50, and in Kent from 3 to 36. The other large returns were Lancashire 64, London 32, Warwickshire 22, Gloucestershire 19, Staffordshire 18, Essex 18, Surrey 17, Yorks West Riding 16, Suffolk 15, Derbyshire 13, Devonshire 13, Cornwall 13, Hertfordshire 10, Oxfordshire 10, Northumberland 10.

In *Scotland* there were 177 more notifications of measles than last week, 127 more of whooping-cough, 20 more of scarlet fever, and 15 more of dysentery. The first three of these diseases were especially prevalent in Glasgow. The largest returns for dysentery were Glasgow 48, Edinburgh 39, Renfrew County 24, Aberdeen 14.

In *Eire* there were 26 more cases of measles than last week, and 7 more of diphtheria, but 23 fewer of whooping-cough. There was an outbreak of 24 cases of measles in Tipperary, Thurles U.D. An outbreak of diphtheria has occurred among the turf workers on the Lullymore Bog in Kildare.

In *Northern Ireland* the notifications of diphtheria were 8 higher than last week, and of scarlet fever 18 higher. The increase in scarlet fever was confined to Belfast C.B. The 22 cases of diphtheria involved fourteen registration areas.

Quarterly Returns for England and Wales

The birth rate during the December quarter of 1944 was 17.1 per thousand, the highest fourth-quarter rate since 1924; the average for this quarter for the five years 1938–42 was 13.9. Infant mortality was 44 per thousand live births—9 below the average of the ten preceding December quarters. The general death rate was 11.8 per thousand, compared with 14.6 for the fourth quarter of 1943, and the same as the average for the December quarters of 1938–42. The natural increase, excess of births over deaths, was 54,958.

The provisional returns for the whole year give the birth rate as 18.0 per thousand, which was 1.5 above that for 1943, and the highest recorded since 1925. Infant mortality was 46 per thousand live births—the lowest rate recorded—and was 3 below the rate of 1943, the previous lowest level. A further small increase in deaths from diarrhoea and enteritis under 2 years of age was recorded; the totals for 1940–4 are 2,891, 2,985, 3,415, 3,517, 3,600. The general death rate was 11.9 per thousand, being 0.2 below the rate for 1943, but 0.3 above that for 1942. The excess of live births over deaths was 253,040; the excess for 1943 was 181,801, and the average natural increase for the five preceding years was 102,620.

Week Ending April 21

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,356, whooping-cough 1,212, diphtheria 565, measles 15,901, acute pneumonia 573, cerebrospinal fever 73, dysentery 523, paratyphoid 3, typhoid 5.

No. 15

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended April 14.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

Rate per 1,000 total births (including stillborn)			25					37		

---

* Measles and whooping-cough are not notifiable in Scotland, and the return are therefore an approximation only.

† Includes primary form for England and Wales, London (administrativ county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birt and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Post-herpetic Symptoms

Q.—*A patient had a severe attack of orbital shingles, not involving the cornea, last October, and is still troubled with intolerable pricking and tingling along the distribution of the supra-orbital branch of the fifth nerve. Various treatments have failed to give relief. What further measures can be tried?*

A.—Irradiation of the skin with ultra-violet light is worth a trial. *X*-ray irradiation can also be tried, but is often disappointing. If the skin is hypersensitive, alcohol injection of the supra-orbital nerve would probably give relief. A preliminary injection of procaine would show whether anaesthetization would be likely to help.

Sterilizing Needles in Oil

Q.—*What are the details for sterilizing needles by immersion in boiling oil?*

A.—The following are the instructions for sterilizing syringes and needles in hot oil given in M.R.C. War Memorandum No. 6, 1942:

"The apparatus necessary consists of a metal cup holding 2–3 oz., held fixed in a rigid stand above a small adjustable gas flame; a thermometer reading to 200° C. clamped to the stand and dipping into the oil (liquid paraffin or olive oil) in the cup. To sterilize a Record type of syringe for use, the needle is taken off and oil at a temperature between 120° C. and 130° C. is rapidly drawn into the syringe. When the plunger is drawn up to the full extent the syringe should be removed from the oil and inverted, so that the hot oil reaches every part of the inside of the syringe. The oil is then expelled, and the process repeated two or three times. Then the needle is affixed, wholly immersed in the oil, and oil is drawn in and out a few times. The syringe is now ready for use. The whole process is complete in 30 seconds or less. When sterilized the syringe can be kept ready for use by wrapping the needle in a small piece of sterile lint. Care is necessary in adjusting the gas flame so that the temperature does not exceed 160° C., otherwise there is an unpleasant smell of burning oil. After some weeks the oil becomes seriously discoloured, and it should then be renewed. This method differs from the other methods of sterilization in that only the needle and the *inside* of the syringe are sterilized. To sterilize needles alone, the cleaned needle is held in the oil for half to one minute. It is then removed with forceps and fixed to the syringe or stored in a suitable container. By this procedure an ordinary steel needle may be in daily use for months with occasional sharpenings on a needle stone."

Posture and Heart Disease

Q.—*Why are heart cases invariably sat up when it is more restful to the heart to lie down?*

A.—Presumably by "heart cases" is meant patients with heart failure. The sitting posture is best because to some extent it relieves any tendency to increase in venous pressure, and also the congestion in the pulmonary circulation. Patients with any degree of severity of heart failure instinctively sit up in order to breathe to the best advantage. There is also less upward pressure from the abdomen on the diaphragm. Plenty of patients with heart lesions who have no failure can lie flat quite comfortably.

Cholecystitis and Coronary Sclerosis

Q.—*The association of cholecystitis with toxic myocarditis is frequent. Is toxic myocarditis with or without coronary sclerosis a contraindication to cholecystectomy? Alternatively, will cholecystectomy arrest or reverse the toxic changes in the myocardium?*

A.—The first sentence rather begs the question. The association of toxic myocarditis with cholecystitis is *not* frequent, and there is no proof that disease of the biliary tract has any influence on the production of heart disease. What *is* frequent is the association of cholecystitis with coronary sclerosis. There is considerable evidence that the diseased gall-bladder increases the liability to attacks of angina, presumably by acting as a reflex trigger mechanism; and, other things being equal, it is for this reason wise to remove a diseased gall-bladder in angina pectoris. There is no proof that patients live longer as a result of the operation, but they certainly live more comfortably.

Mooren's Ulcer

Q.—*What is the most up-to-date and/or successful treatment for rodent ulcer (Mooren's ulcer) of the cornea?*

A.—True Mooren's ulcer is so resistant to treatment that any success makes one doubt whether the diagnosis is correct. Two recent successes have been obtained—the first by the use of sulphathiazole ointment, 5%, with bandaging of both eyes, and the second (where the other eye had been enucleated for the same condition) by carbolization, conjunctival slide, and tarsorrhaphy all at the same time. Application of radium has been suggested, but should be used with extreme care owing to the vulnerability of the ocular tissues to radium. Short-wave and ultra-violet-light therapy have not met with success.

Catgut and Wound Infection

Q.—*What is the pathological mechanism involved in the predisposition to wound infection by the use of catgut? Is it merely that catgut may not be sterile?*

A.—Is it true to say that there is predisposition to wound infection by the use of catgut? The process of absorption of catgut is one of inflammation, with exudation, round-cell infiltration, and the appearance of foreign-body giant cells, but this does not signify infection. Nor is it correct to assume that catgut cannot be sterilized. When prepared for surgical use under the conditions laid down by the Ministry of Health, catgut is sterile, and there is now no excuse for the surgeon who uses catgut which is unreliable in this respect.

Mervyn Gordon Test for Smallpox

Q.—*What is the Mervyn Gordon test for smallpox, and to what extent is it reliable?*

A.—This is a flocculation or precipitation test. The one usually employed is Craigie and Tulloch's modification of the Mervyn Gordon test. A series of saline extracts of dried crusts from a suspect case are added to various dilutions of serum obtained from a rabbit immunized against vaccinia. If flocculation occurs in the mixture after incubation it indicates the presence of the smallpox or vaccinia virus. No flocculation occurs with a suspension obtained from chicken-pox crust. The test is thus of practical value in distinguishing chicken-pox from smallpox in the crusting stage of the disease.

Prognosis in Otosclerosis

Q.—*What advice should be given to a patient regarding the prospects of relief from deafness due to otosclerosis?*

A.—The general opinion is that no operation yet devised has given worth-while results in more than a minute proportion of cases. It is possible that improved technique will in the next few years give results which justify the small but definite operative risk—but that time has not yet arrived.

Polyneuritis in Pregnancy

Q.—*Sometimes pregnant women—usually the hard-working poor, but not necessarily under-nourished—suffer from a type of neuritis affecting the hands and occasionally extending up the arms. There is a numbness and sometimes "deadness" in the fingers, accompanied perhaps by either swelling or pain. What are the cause and treatment of this condition?*

A.—The patients described in this question are undoubtedly suffering from polyneuritis, a condition which is very common in pregnancy. The most severe examples are seen in cases of hyperemesis gravidarum, and the neuritis may come on after apparent recovery. Severe cases have also been reported in patients not suffering from hyperemesis. Deaths from this condition have been reported, and in other cases the nerve lesions have become irreversible and have led to permanent paralysis. These serious cases are fortunately *very uncommon*, but milder types of the disease are common and lead to a good deal of suffering and disability.

Polyneuritis of pregnancy has now been established as being due to deficiency of vitamin B_1. It has been shown by Helen S. Lockwood, S. Kirkwood, and R. S. Harris (*Amer. J. Obstet. Gynec.*, 1943, **46**, 358) that the requirement of thiamine (vitamin B_1) is increased threefold in pregnancy and the puerperium. In addition, a high intake of carbohydrate such as is likely in a wartime dietary will further increase the thiamine requirements. Another possible factor is deficiency of hydrochloric acid in the gastric juice, and it was shown by M. B. Strauss and W. J. Macdonald (*J. Amer. med. Ass.*, 1933, **100**, 1320) that achlorhydria is commonly found in association with polyneuritis of pregnancy. It is suggested that the questioner should treat his patients with large doses of vitamin B_1. L. S. McGoogan (*Amer. J. Obstet. Gynec.*, 1942, **43**, 308) recommends administration of 50 to 100 mg. of thiamine hydrochloride daily. In addition hydrochloric acid (one fluid drachm of acid. hydrochlor. dil.) may be given with meals. This should be taken well diluted in water or lemonade.

Pregnancy after Perineal Operations

Q.—*A woman of 30, healthy and strong, who was confined a year ago, has just been operated on for cystocele, rectocele, and perineorrhaphy. What advice does one give on future confinements? How soon may she safely conceive, and are there any special precautions? Her only confinement, which took place a year ago as above mentioned, was a non-instrumental delivery, but she had seven stitches. Before the operation she was fitted with a ring, but even a No. 12 dropped out when she stood up.*

A.—She should wait at least six months, and preferably one year, from the time of the operation before embarking on another pregnancy. If the cervix was not amputated there is no reason to expect any special complications during another pregnancy, but during the second stage of labour the vagina and perineum may not distend easily, because of the scars. The chief concern should be to avoid a recurrence of prolapse, and to this end episiotomy should be carried out as soon as the head is beginning to distend the perineum. The incision should be a liberal one, beginning at the fourchette just to the side of the perineal scar and extending backwards and slightly outwards to the side of the anus. It will, of course, need to be carefully sutured, layer by layer.

Radio-active Hair Tonic

Q.—*A patient has been using a proprietary hair tonic for which it is stated that: "The preparation is activated by actual radium element to a radio-activity of 2,000 Macbe units = 555,60 milli-micro-curies ($\pm$20%) per gallon." I should be glad to know what this means, and whether any injurious effect is likely to result from the use of the "tonic." Is there any Act operating which prevents the sale of radio-active substances to the general public?*

A.—The stated radium content of the preparation is about 10^{-4} mg. per litre, and no local injurious effect is therefore likely to be observed unless the preparation was continuously used for several years. The gamma-ray activity, however, approaches the tolerance dose of 10^{-5} r/sec. recommended as the safety limit by the British *X*-ray and Radium Protection Committee, so that some general effect, such as a leucopenia, might be observed after prolonged use. So far as I know, there is no Act prohibiting the sale of radio-active substances to the general public.

A Case of Arthritis

Q.—*A woman, aged 74, two years ago had a serious illness, which started with severe facial neuralgia. Teeth were x-rayed and 6 were extracted. The neuralgia became worse, the temperature began to rise, never higher than 102° at night, but continuing for 2 to 3 months. This was diagnosed as a subacute septicaemia following tooth extraction. After sulphonamide therapy the fever subsided and the neuralgia disappeared. About a year ago pain and stiffness in the right thigh began, especially after walking a short distance and uphill. The pain is located on the outer side of the thigh, to a lesser extent on the inner side and back. Some years ago the ankle on the same side was sprained, and the plantaris has been ruptured twice. Flexing the thigh causes pain, so that going upstairs means one step at a time using only the left leg. There is a thickened plaque to be felt on the outer side and middle of the thigh, about 2½ in. in diameter—this can be dispersed by fairly heavy massage. It is very tender to the touch. There are other tender spots, one near the great trochanter, sometimes one in front near the patellar attachments, but no obvious lumps at these places. The general health is good.*

A.—The details of the case are interesting though difficult to link up into a complete and uniform picture. I think there is little doubt that there is arthritis of the right hip, possibly infective at the outset; but now the active phase has died down and there is a chronic osteo-arthritis which, as is so often the case, gives rise to pain referred to other parts of the thigh rather than to the joint itself, comparable with the referred pains which characterize tuberculous arthritis of the hip in childhood. *X*-ray examination is, I think, essential to the formation of a definite diagnosis, but in its absence, and without the opportunity of making a clinical examination, I feel that this view of the case is correct.

The thickened plaque on the outer side of the thigh is not easily explained; it would appear to be associated with the ilio-tibial band and possibly due to the bursa which often lies between it and the femur. If there is effusion into this bursa it might be dispersed by heavy massage. The congested fatty layer described by Copeman and Ackerman as occurring in the back might also give rise to the same symptoms, but anything like a formed fibrositic nodule could not be got rid of so easily. Its tenderness and tendency to recur would be readily explained by a bursitis or tenosynovitis. Flexing the thigh would cause pain in arthritis of the hip, but grating is unlikely at this stage, and in any case is not commonly felt in osteo-arthritis of the hip. As I have frequently to emphasize to students, trouble in the hip causes pain going uphill, whereas if it is in the knee the pain is felt when going downhill; referred pain in the knee is usually at the inner side and is due to being referred along the obturator nerve which supplies both joints. Fibrositis is a common accompaniment of osteo-arthritis, usually peri-arthric in site but not invariably so, and is certainly affected by climatic conditions, so there is some prospect of relief in a dry climate. A walking calliper seems to be the most likely method of relieving the pain and allowing the joint to settle down, but some degree of permanent lameness is, I think, inevitable. Some patients regard a calliper, however, as worse than the trouble it is designed to treat. The less walking the better, but daily movement of the joints to their full extent is necessary to prevent their becoming limited in range.

Drugs, except aspirin, are not likely to help, but heat and massage will be useful, and the best form of heat will be hot hip baths with washing soda—a small handful to the gallon would be strong enough. If the soda irritates the skin mag. sulph. might be a good alternative. The history of previous damage to that leg will account for its being attacked now. It is usually the damaged joint that becomes the seat of further trouble and not the sound ones. At the age of 74 the possibilities of relief are limited.

LETTERS, NOTES, ETC.

Old Books in the Market

The library of the late Sir Buckston Browne, F.R.C.S., which is to be sold at Messrs. Sothebys on May 8, contains a few surgica and anatomical treatises of the seventeenth and eighteenth centuries; three of these are of bibliological interest, two of them of specia appeal to a urologist such as Sir Buckston. These three are the first French translation of Sir Thomas Browne's *Religio Medici*, published in 1668 under the title of *La Religion du Medecin;* the anonymous tract published from Wyllyam Myddyton's press (in 1544), "Here begynneth the seynge of Urynes of all coloures that Urynes be of with the Medycines annexed to every Uryne and every Uryne his Urynal much profitable for every man to knowe"; and Rober Record's "Urinal of Physick, whereunto is added an ingenious treatise concerning Physicians, Apothecaries and Chyrurgians' published by Gartrude Dawson in 1651. A number of the eighteent century books are connected with the Plague.

A Seminological Laboratory

Practitioners who deal with sterile couples may be interested t know of a new laboratory which offers facilities for seminal examinations and for post-coital examination of the cervical mucus Increasing numbers of women who attend Family Planning Association centres are seeking advice on the treatment of involuntar sterility. Whilst this type of case has been welcomed at the clinics in most cases advice given has inevitably been curtailed by the lac of facilities for getting competent seminal investigations at fees suitable for such patients. The Sub-Fertility Committee of the Famil Planning Association has therefore been working to establish pathological laboratory, which has now been opened under th charge of Dr. H. A. Davidson, at 33, Wimpole Street, London, W.1 There have, up to the present, been very few laboratories in thi country which include in their technique measurements of th viability of the spermatozoa, both *in vitro* and in the cervical canal This factor may be of the utmost importance in certain cases o sterility. Studies in seminology have been carried on in connexio with the Exeter Clinic by Mrs. Clare Hervey, and work at the Londo laboratory is expected to develop along similar lines. Workers o sterility have always been hampered by differences in methods o examining semen, which make it impossible to compare results fro different laboratories. Mrs. Hervey's aim has been to evolve standard technique which should overcome this difficulty. If, a the Association intends, it becomes possible to open laboratories i other parts of the country, a large amount of comparable dat should soon be collected for study. The London laboratory wi undertake investigations for clinic patients at especially low rates Its services are also available for private practitioners who wish t have cases investigated.

Calcification of Supraspinatus Tendon

Dr. P. W. **Hampton** (I.O.M.) writes: I was interested in th answer on calcification in supraspinatus tendon in the *Journal* o March 31 (p. 468). During the last war I was consulted by a elderly officer who complained of pain in the shoulder which wok him at night if he happened to turn over on that side. *X*-ra examination showed what looked like a bony spur growing fro the greater tuberosity of the humerus. At operation the spur wa found to be somewhat pultaceous and was easily scraped out with Volkmann spoon. I took it to be a tophaceous deposit, and, c later asking the patient if he had ever suffered from gout, he to me that some years previously he had had a gouty testicle remove

WAR NEUROSES AFTER PSYCHOLOGICAL TRAUMA

BY

R. D. GILLESPIE, M.D., F.R.C.P.

Air Commodore, R.A.F.V.R.; Physician for Psychological Medicine, Guy's Hospital

The argument falls under two heads: (1) That a psychoneurosis, or, more correctly, a mental or a combined mental and physical disturbance, may be produced by a sudden frightening experience, and that this neurosis may be of a type which ultimately presents no symptoms except those produced episodically by associative arousal by some reminder of the original traumatic experience. These episodic symptoms may, however, be disabling while they last. (2) A traumatic psychoneurosis, either in this special sense or with persistent and not mainly episodic symptoms, may depend on either (*a*) a disturbance nearer the physiological level, depending on properties common to all organisms; or (*b*) a disturbance mainly at the psychological level, depending on the particular type of personality, especially the ego-organization, whether anxious, hysterical, or what-not.

"Traumatic neurosis," in the sense of a mental or a combined mental and functional-physical disturbance of some kind following a psychological stimulus from without, usually implies two things: that the event impinges suddenly, and that the subsequent disturbance persists for some time. In a war the provocative stimulus is usually one of fear, less often one of horror, or both combined.

The present study was prompted by a doubt whether in the case of flying personnel we know all we should know about psychiatric disabilities after flying accidents and terrifying experiences in combat, and whether we may do less than justice from the medical aspect in some cases in which disciplinary problems arise. The individuals studied presented no history suggesting head injury, or at most a very transient impairment of consciousness after the accident.

Three main kinds of speculation have been invoked to help in the understanding of the traumatic neuroses: (*a*) hypotheses based on biological analogies, especially the comparison of stupor following fright with the immobility reactions of animals; (*b*) speculations based on neurophysiological considerations, mainly Pavlov's (1928) formulations; (*c*) psychopathological and especially psycho-analytic speculations.

The first does not help us much except perhaps with regard to such transient stupors as those described by Hubert (1941). They might be regarded from this standpoint as regressive phenomena. Rivers (1920), in the last war, extended this analogy of sham-death to partial reactions, such as the immobility of a hysterically paralysed limb.

Pavlov's (1928) physiology offers a more seductive kind of analogy. The observation that reminders of a shattering experience may still produce mental reactions is of course very old. For example, Sir John Fortescue mentions that a lady who had been in the siege of Lucknow, in which her husband had been killed, and who had since remarried, would still, years afterwards, turn pale and tremble at the very mention of the place. This phenomenon of the "conditioned reflex" in its various elaborations can be applied in an interesting way to a description of war neurosis in general in Pavlov's and, to a lesser extent, in Sherrington's terms. Thus Love (1942) speaks of fear as a reflex, and increasing susceptibility to fear as due to facilitation of this reflex. He also suggests that the prolonged inhibition of fear may itself lead to a neurosis, just as delayed inhibition leads to an experimental "neurosis" in Pavlov's dog. This has been extended by Symonds (1943) to sudden traumatic experiences, when the individual seems to have been unaware of fear at the time but develops psychoneurotic symptoms some time (perhaps a day or two) afterwards. Pavlov's (1928) observation that ultramaximal stimuli, instead of producing excitation, produce the paradoxical result of inhibition, might be invoked to explain the phenomenon of stupor resulting from terrifying experiences.

The psycho-analytic view as propounded originally by Freud (1922) appeared to be concerned primarily with accidents in which some sudden physical stimulus impinged on the body surface. He says: "I think one may venture, tentatively, to regard the ordinary traumatic neurosis as the result of an extensive rupture of the barrier against stimuli." In this way the old doctrine of shock would come into its own again, apparently in opposition to a later and more psychologically pretentious view, which ascribes aetiological significance not to the effect of the mechanical force but to the fright and the menace to life. He pictures the stimulus which has broken through the barrier as having to be "bound" by charges of energy drafted from elsewhere in the organism. What conditions fright is the failure of the "mechanism of apprehension" to make the proper preparation, including the overcharging of the system first receiving the stimulus. The dreams of patients suffering from traumatic neuroses are attempts at restoring control of the stimuli by developing apprehension, "the pretermission of which caused the traumatic neurosis." This suggests the paradox that the greater the apprehension the less the likelihood of developing a traumatic "neurosis." There may be some truth in this in that it appears, according to my observations, that anyone, no matter how stable he may be, may develop a traumatic neurosis in the sense of recapitulatory dreams and "conditioned" responses if the traumatic experience is terrifying enough, while individuals of more anxious temperament are more apt to develop increased apprehension and the ordinary symptoms of anxiety. Freud (1922), however, adds that the traumatic neuroses of war may arise more easily as the result of ego-conflict. Following this hypothesis, Kardiner (1941) believes that a psychic trauma may leave the ego handicapped or restricted in its adaptation to the external world.

I suggest that there is some truth in all these theories and that there are at least two types of psychoneurotic response to a terrifying stimulus—one depending more on the physiological properties common to the nervous systems of all individuals, and another depending on the psychological aspects of the personality. There is no "unnecessary dualism" here; it is simply that one type of response is at present describable more in physiological terms and the other in psychological. They can be regarded as occurring at different levels of personality-integration.

"Simple Traumatic Neurosis"

The central feature of the classical traumatic neurosis has been the recurrent dream which recapitulates the traumatic event. Freud (1922) made it the point of departure for his observations on the repetition-compulsion phenomena. It

4401

would not invalidate his speculations on repetition-compulsion if this kind of dream were to be found to depend not on disturbance of the organization of the ego but on more primitive properties. It would not be the first time in the history of medicine that a correct conclusion had been reached from a mistaken premise.

This type of dream may be regarded instead as a perseverative phenomenon at the physiological level. It can occur in mature personalities and it gradually dies out, like the fading of any other memory. That such experiences can persist in an engrammatic fashion is suggested by an observation of Penfield and Ericson's (1941). An epileptic girl aged 17 had had a fright at the age of 4 when a man came up behind her; she ran from him across a meadow to rejoin her brothers. Afterwards she had nightmares in which the scene was re-acted. Some time later she began to have attacks in which she showed fright, screamed, and clung to people, and these were followed by a major seizure. During the fright she saw the same scene, and was filled with terror lest she be struck or smothered from behind. This hallucination could be exactly reproduced by electric stimulus of the middle temporal gyrus.

The recurrence of a dream of a traumatic experience could be attributed to a similar automatic activity of a neural engram at a time when, as in sleep or in epilepsy, the inhibitory effect of the cortical activities is in abeyance. The occurrence of dream-like experiences, depending on a release of the cortical control, has been noted by Lhermitte and Tournay (1927) and others in mesencephalitic lesions.

In traumatic neuroses in stable individuals I would place alongside the recapitulatory dream at this lower physiological level a conditioned response to anything nearly recalling the original trauma. What presumably produces them both in the first place is the arousal of the fear apparatus of the organism. There is evidence that this is stimulated even in the absence of conscious fear. Anyone who has been through a sudden frightening experience knows that immediately the crisis is over a variety of bodily sensations, such as palpitation, tingling, tremor, etc., make themselves felt. These occur so immediately as not to be produced by rumination. They occur automatically in response to the perception of danger. The other kind of evidence for the arousal of automatic fear reactions is the observation that bodily disturbance can be produced by some reminder of the original trauma in the absence of conscious mental disturbance. For example: An R.A.F. pilot, walking in the country, was suddenly aware of palpitation and uneasiness. He could not understand this until he realized that a certain smell that he had just whiffed was associated in his mind with the smell of burning flesh in an accident in which he had been involved (Lees, personal communication). It is to be supposed, therefore, that the immediate stimulation of the emergency physiological processes may influence, by "stamping-in," the visual perceptions at the time, even in those cases in which the individual is not consciously afraid.

This last instance is an example of the other traumatic effect in Freud's discussion which is not taken account of, but which is more upsetting because more persistent than the recapitulatory dream—namely, the conditioned response to any reminder of the traumatic event. We are accustomed to think of "conditioned responses" in the Pavlovian experiments as being established only by repeated training; but it is a commonplace observation that they may be founded on a single experience, if it be intense enough. Horsley Gantt (1943) confirms that the same effect can be produced in an experimental animal. The phenomenon is not identical with the "startle" response to a loud noise; it is specific to associations with the original stimulus.

The following instance, I suggest, is typical of a "traumatic neurosis" or psychoneurosis produced in the way described.

An air gunner, aged 32, on the first occasion on which he flew in a rear turret (where one is entirely enclosed and separated from the rest of the crew) panicked and emerged from the turret into the body of the machine "blowing like a grampus"—as the others described it. He had been seized with panic at being shut in, but could not at first account for this. He was a well-built man of apparently stable temperament. His history, however, revealed that at the age of 15, just after he had started work in a large stores, he had an unusual and terrifying experience. His duty every Saturday afternoon was to place the books in the strong-room. On this particular occasion the door of the strong-room locked behind him and he found himself inside, with no apparent prospect of release till the following Monday. He began to feel that the atmosphere was getting more and more suffocating, and he became more and more frightened, until at last he realized that if he smashed a small red electric bulb he could sound the alarm and bring attention to himself. After he had been confined for about two and a half hours the door was opened by a watchman and guard armed with carbines, who naturally thought a burglar was inside.

He slept badly for some time after this episode and had nightmares recapitulating the experience. These gradually ceased, and the only symptom he could recall in the ensuing years was some uneasiness in confined spaces; for example, in buying a car of his own he had always chosen a roadster, as he was uncomfortable in a sedan.

The episode in the air was evidently an attack of panic depending on a "conditioned" associative arousal of the old experience. His heavy breathing was presumably related to the original fear of suffocation.

The deduction that suggests itself is that a condition which is otherwise symptomless may be disabling in specific situations. The reaction is automatic and independent of motive. It is important to note that the reaction which was produced included not only visceral components but conscious fear, of disabling intensity, as part of the reactive traumatic pattern. The similarity to Penfield and Ericson's (1941) case is suggestive, although there the releasing factor was the epileptic process.

Injustice would be done in such a case if the man were returned as fit because he complained of no symptoms in the ordinary sense. Someone may object that it is impossible to be certain that he was not motivated by a desire to avoid flying. One could only reply that evidence for this was lacking.

There are parallel instances where it seems possible to exclude motive, conscious or unconscious. A merely anecdotal example is Fortescue's story, already recounted; but documented examples are available from war experience. A W.A.A.F. officer, aged 39, who had been bombed out, had recapitulatory nightmares and retched a good deal. Long after the 1940–1 air raids had ceased she would retch again if she saw a chimney-pot damaged or a slate dislodged. She found it impossible to attain voluntary control of this symptom.

It seems justifiable, therefore, to suggest that an automatic, unmotivated, conditioned responsiveness may be produced by any sudden terrifying experience, such as an aircraft crash. The following is an example:

Sgt. A., an air gunner with 200 hours' flying to his credit, of which 40 had been spent in night flying, complained of loss of confidence and fear of night flying; he said he never got the feeling by day. Nine months previously he had been in his first night flight of any duration. The aircraft crashed on landing; he was trapped in the back of the machine and had to wait for people to cut him out. He wondered whether there would be a fire, but does not remember feeling particularly scared at the time. He dreamed of the crash afterwards, but otherwise showed no symptoms on the ground. In the air, however, he found himself in a state of acute apprehension, which increased with each attempt to fly. There was no evidence of timidity or any special tendency to anxiety in his previous history.

The argument, so far, is as follows: (1) There is a specific response to terrifying experience, not dependent on psychological attributes, but occurring more nearly on a physiological level. (2) This response consists principally of a recurring nightmare reduplicating the experience more or less exactly, and of a conditioned or associative response to stimuli resembling or in some way recalling the original experience. (3) Such a condition can exist independently of motive or volition. (4) The dream usually dies out, but the conditioned response is apt to persist indefinitely, without any other symptoms. (5) The response when re-aroused may involve only visceral reactions, or it may disturb consciousness as well by producing difficulty in concentration, together with conscious fear. (6) The result may be a condition specifically disabling for certain tasks—e.g., flying an aeroplane. (7) This theory may explain the good performance of such individuals in other circumstances—e.g., in the Army—afterwards.

As accessory symptoms there may exist a loss of emotional control, resulting in a form of irritability, but probably more often in some degree more generalized. Thus one man described his whole attitude as "excitable" and "fussy."

Anxiety and Other Psychoneuroses after Trauma

In individuals whose ego-organization is not stable, who are either anxious or narcissistic, the response to a traumatic experience may include the above characteristics, but it is usually shown either in persistent anxiety symptoms or in hysterical ones. In fact, in some apparent contradiction to Freud's (1922) original notion, those who are "prepared" with anxiety for any threat to existence are more apt to develop a psychoneurosis afterwards.

The following is an example of psychoneurosis after psychological trauma in which symptoms of anxiety and apprehension predominate. In such instances the traumatic experience probably simply accentuates a pre-existing state of anxious anticipation:

Sgt. B., aged 34, an air gunner under training with 30 flying hours in his log-book, was involved in an aircraft crash. He does not remember the machine actually hitting the ground; the first thing he remembers was that the aircraft was on fire and that he was being pulled out. Then "something blew up" and he was for a brief period unconscious. The next thing he remembers is being in an ambulance. He said: "When I came to and found the aircraft was on fire I looked round for a hatchet and was very calm. I still couldn't get out, and was reconciled to being burned. I was not worried. Then when I heard someone trying to get in I began to want to get out. Then he ran away, and this worried me; but he came back. I remember screaming 'Come back,' but up till then I didn't seem to worry what happened—I was more or less contented."

His symptoms now consisted of a "confined feeling" in the head, insomnia, pain in the back of the head, nervousness in any closed space, whether a bus or a building, and difficulty in concentrating and in remembering. He was obsessively preoccupied, not with the accident but with the idea of flying again. He felt relief in contemplating a newspaper photograph of a peaceful rural scene. "I look at the photograph and I feel more confident; it's peace and quiet." In temperament he was timid, anxious, a poor mixer, emotional, and meticulous in his habits.

The main points are: his timid and anxious temperament, his vivid recollection of the crash, the preliminary moments in which he felt no fear, followed by panic; and the subsequent persistent anxiety reactions coupled with a conditioned response to closed spaces.

Both types of reaction may occur in the same individual, as in the following instance, combining the pure traumatic effect of dream and conditioned responses plus anxiety symptoms arising out of an insecure and dependent personality in whom there is evidence presumptive of unresolved infantile conflict.

An officer, aged 36, complained of insomnia with nightmares and drenching sweats, inability to concentrate, dislike of meeting people, and a tendency to worry about everything. He had become worse since he had received notice of a posting away from his present unit, which is stationed near enough to his home to enable him to live out. His personal history was that he grew up with the feeling that he was not wanted by his mother. Her entire affection was bound up in his sister, who is now, as he says, a complete contrast to himself—"a care-free strapping girl." For the first six years of his life he was brought up by his grandmother. His father realized the mother's attitude and tried in some ways to atone for it, but, on the other hand, he was a severe disciplinarian who often beat the boy.

As a child he was nervous of being left alone. He was exposed to air raids in London during the last war and was extremely afraid of them. He walked in his sleep a great deal; on one occasion he lit a bonfire in the grounds of the house, and on another occasion he wandered down the road and was brought home by a policeman. His mother used to lock him in his room to stop this, and he experienced great terror when he woke up during his sleep-walking in his attempt to get out of his room.

At school, in his younger days, he was the butt of the others, as he was always dressed differently. He made friends readily enough and played the usual games, except for a period between 14 and 16, when he had to wear a truss. He was a good swimmer.

He has, to this day, disliked the limelight; he likes to work "behind the scenes," as he put it. In spite of this he had a successful business life, became a very hard worker and conscientious in an obsessional way, although he is not severely obsessional in his mental habits; he dislikes dirt extremely and has a distaste for untidiness. He has always been capable of self-discipline, even to a punishing extent. For example, in his boyhood he would go to early morning service at church, without breakfast, and while kneeling in church in these circumstances he fainted several times. This ardent church attendance was connected with his admiration for a prominent preacher of the time, with whom he became close friends. When the war started he became an A.R.P. warden; he experienced a considerable number of air raids without being disturbed in his efficiency and in spite of loss of sleep.

He enjoyed his work in a non-flying branch of the R.A.F., remaining fit until Jan., 1943, when he had an attack of influenza, followed by jaundice. He still felt unwell on his return to his unit, which was raided on March 9, 1943. There was a "near miss" on the hut in which he was. He remembers no fear at the time; in fact, he remembers realizing that the bomb was going to land very close and reconciling himself to what he thought was the inevitable end. He was bruised by falling debris, and remembers that he had the very greatest difficulty in preventing himself from running instead of walking to an adjacent shelter, but he slept perfectly well that night. At breakfast in the morning, however, he felt disinclined for food, and in the afternoon of the day after the bomb fell, when a siren went again, he found himself, to his surprise, very much affected, feeling extremely afraid and experiencing great difficulty in controlling himself so as not to show signs of fear in front of his brother officers. Since then he has suffered from the symptoms of which he now complains. His nightmares are not usually about bombs, but about drowning or being strangled, and he wakes up in such a profuse sweat that his pyjamas are soaked.

After this condition developed he succeeded in getting a post to a station where he could live out, at home with his wife. Previously it had not been an ordeal to be away from her, but now he found himself very dependent on her support and comfort. There were no air raids in the vicinity of his unit, but an air-raid siren went off every Sunday morning as a practice. He observed that he inevitably reacted with feelings of tension and anxiety until he reminded himself that it was not a sign of an actual air raid, and his commotion subsided to the level which is now habitual, as he described it in his symptoms.

NOTABLE POINTS IN THE ABOVE CASE

1. The patient was a good example of a child suffering from rejection by his mother, with anxiety symptoms in his childhood which were probably closely related to this situation, and with a chronic sense of inferiority, also originating in all probability in the same way. His marriage to an older woman was probably determined a good deal by lack of the maternal type of affection in his boyhood, but it should be noted that his dependence was not so extreme that he was unable to live with reasonable happiness apart from her until after the air-raid experience of March, 1943. No doubt the anxiety reactivated by this traumatic experience could be construed as separation anxiety, revived.

2. There is no question of lack of courage, since he had endured many previous air raids with success and taken an active part in the work of defence.

3. His sense of duty has some of its roots in his obsessional characteristics, which may again be related in some degree to his upbringing by an unaffectionate mother and an affectionate but severe father. His excessive conscientiousness shows itself in his reaction to his present symptoms; he says: "I am thoroughly ashamed of this—I am yellow."

4. The air raid which upset him occurred at a time when his general health was impaired and therefore his resistance, both physical and mental, lowered.

5. During that episode he had no awareness of fear of the bombs approaching, although immediately afterwards he noticed that he had difficulty in controlling the impulse of flight. It is notable, also, that he slept quite well on the following night and that there was a latent interval between the experience and the development of symptoms. Furthermore, the symptoms appeared not to develop to any disturbing extent until another stimulus occurred—namely, an air-raid warning recalling the previous experience. It is virtually certain that this air-raid warning signified to his mind, at the time, another air raid, and that, unlike the practice warnings at his new unit afterwards, it had a definite meaning of danger for him. It is to be observed also that subsequent air-raid warnings, although rapidly recognized as innocuous, continued to produce exacerbations of his now chronic emotional tension. Moreover, his symptoms of chronic tension have persisted in spite of his being away altogether from reminders in the shape of actual raids or danger of any kind.

Additional Points on Cases

1. It is notable that most R.A.F. crew members who have been involved in a flying accident seem to remember the traumatic experience vividly and in detail. This is contrary to Kardiner's observation; but his cases were of much longer standing—years, instead of weeks or months, having elapsed since the event. It is probable that hysterical processes entered far more often into the psychodynamics of his group.

2. There is, in a considerable proportion of the cases coming under my observation, retrospective evidence that there was conscious fear at the time of the occurrence. "Delayed inhibition" in the Pavlovian sense does not seem to have been the process responsible in them for the subsequent psychoneurosis.

3. It is possible that some stupors are essentially states of extreme preoccupation with the frightening experiences (cf. Hoch's (1921) *Benign Stupors* and the preoccupation with death).

4. Other stupors are presumably hysterical (avoidance) methods of dealing with the same kind of experience.

5. The long persistence of conditioned responses after trauma, up to two years in some R.A.F. cases, and probably indefinitely longer, has its parallel (Anderson and Parmenter, 1941) in sheep with experimental neuroses.

6. Some phobias, not of war origin, have probably the same kind of basis, extended to other situations recalling the original traumatic one in some way.

I have to thank Air Marshal Sir Harold Whittingham, Director-General of Medical Services, R.A.F., for permission to publish this article.

GAS GANGRENE

WITH SPECIAL REFERENCE TO VASCULARIZATION OF MUSCLES

BY

R. WOOD POWER, F.R.C.S.I.

Lieut.-Col., R.A.M.C.

The various factors in the pathogenesis of gas gangrene have still to be assessed. Of these, muscle ischaemia, while generally recognized as playing a part, has not received the attention it deserves. The present paper attempts to elucidate some of the problems of surgical treatment, with particular reference to the possible effects of vascular injury in promoting gas gangrene in war wounds.

Out of a series of 6,000 wounded 20 cases of gas gangrene were encountered in this general hospital during the first two months of the fighting in Normandy. It is seldom that the surgeons of a large general hospital have had the opportunity provided in this beach-head of seeing their patients within six to eight hours of wounding, of undertaking the primary surgery, and of observing the sequence of events at first hand from day to day. Adequate notes are available in 16 of the 20 cases encountered, and in only one of these had the initial operation been undertaken at a forward C.C.S.

Three factors are essential for the establishment of gas gangrene—the presence of pathogenic clostridia, an adequate mass of ischaemic or necrotic muscle, and delayed or faulty surgery. The first two are unavoidable, and can be effectively countered only by early adequate surgery. When casualties are heavy it is impossible to operate on all cases within the optimum period, but if those likely to develop gas gangrene are given priority it would go a long way towards eradicating this disease. Apart from gross destruction of a limb, gas gangrene is most lethal in the thigh and buttocks, and all cases of shell wounds in these areas should be given operative priority.

Muscles are supplied by one or more arteries. Should one of these be injured, then that part of the muscle supplied by the injured vessel becomes ischaemic. When this occurs the re-establishment of the collateral circulation within the muscle appears to be extremely slow, and in open wounds invariably results in necrosis. This not only is borne out by my own operative experience, but has recently been proved experimentally in rabbits by Le Gros Clark (1945). He states: "After ligature of the lower vessel of supply to the tibialis anticus . . . the normal vascularization of the lower half of the muscle is not restored for about a week. If both of the main vessels supplying the tibialis anticus are ligatured revascularization is delayed for a fortnight." And again: "In spite of anastomotic connexions, the interruption of one vessel of supply to a muscle (or one of its branches) may lead to a relatively extensive and well-defined area of ischaemia lasting for several days. This is important in relation to the infection of muscles in war wounds." I would go further and state that, combined with the presence of clostridia, it invariably results in gas gangrene.

I have stated that sufficient ischaemic or necrotic muscle is essential for the establishment of gas gangrene, and the following examples illustrate this. In the first, a small ragged piece of shell passes through the thigh, causing no arterial damage; it leaves in its wake a tract thinly lined with avascular muscle. Such cases, whether operated upon or not, will not develop gas gangrene: natural resources can cope with such damage. Now, if a similar piece of shell passing through the thigh should strike an artery—say the profunda femoris—we have a very different picture. Two groups of muscles are rendered ischaemic and form a suitable pabulum for micro-organisms. If clostridia are present in such a wound gas gangrene will be extensive and rapidly fatal; only early adequate surgery can be life-saving. On the other hand, should a smaller artery be lacerated—say one of the perforating branches of the profunda femoris—then a more limited area of muscle is rendered bloodless. In such a case gas gangrene, if it develops, will be less extensive and not so rapidly fatal. Such examples are often met with in war surgery, and they illustrate the paramount importance of the total exploration of all shell wounds, however small.

A surgeon who fails to remove significant quantities of ischaemic muscle is guilty of faulty surgery, for gas gangrene is very likely to develop. The thigh is more sinned against in this respect than any other part of the body, and failure to carry out adequate surgery in this region has been responsible for most of the recorded cases of gas gangrene in this war. Muscle deprived of its blood supply for six to eight hours dies. If operation has not been undertaken within this period all bloodless muscle must be excised. If one group of muscles is avascular it should be removed; if two groups are involved the limb should be amputated.

Of the 16 cases under review 14 occurred in the lower lim and 2 in the upper. The disparity is accounted for by the more abundant arterial anastomosis of the arm and by the relative vulnerability of the leg owing to its greater mass. I will be found that the cases come under two distinct categorie —namely, massive gas gangrene resulting from damage to the main artery of a limb, and localized gas gangrene (in the early stages) resulting from laceration of muscular branches. Seve of each type occurred in the lower limb and one of each i the upper, as tabulated below. There were two deaths, bot resulting from gas gangrene following injury to the poplitea artery.

	Main Arterial Damage	Injury to Muscular Branc
Upper limb	1	1
Lower limb	7 (two deaths)	7

Upper Limb

1. *Case of Main Arterial Damage.*—Cpl. A. was wounded in th abdomen and right elbow on June 29, 1944. He was in a forwar position, and was not rescued till the morning of July 2—60 hour after being wounded. On admission to hospital the same day h condition was fair. He had an intestinal fistula and did not com plain of abdominal discomfort. There was a foul-smelling woun on the anterior aspect of the elbow, the skin was mottled, and t arm above and below the elbow was greatly swollen. Rigor mort

had set in in the hand; it was impossible to move any of the fingers. Amputation above the elbow was carried out the same day; the abdomen was not disturbed. On exploration of the amputated limb the radial and ulnar arteries were found to have been severed just below the bifurcation of the brachial artery; anaerobic myositis was found in the muscles of the upper forearm.

If the radial and ulnar arteries are severed below the recurrent branches the forearm is cut off from all blood supply and early amputation should be performed: two similar cases were encountered in which both arteries had been ligatured and amputation was carried out later. Ligature of the brachial artery, on the other hand, does not necessarily endanger the life of the limb: in three cases the artery was ligatured in the region of the elbow, and in all of them the limb survived.

2. *Injuries to Muscular Branch.*—L/Cpl. B. sustained a shell wound on the outer aspect of the arm on July 18, 1944. The entry wound was small; there was no exit wound. When seen, 20 hours later, gas gangrene was well established. On opening up the arm the long head of the biceps was completely gangrenous and was the only muscle involved; it was removed *in toto*. The upper tendinous part was first cut through and the muscle dissected out towards the elbow. On reaching a point about the middle of the arm, where the shell fragment had pierced the muscle, an artery was encountered. It was a branch of the brachial, which, having passed through the short head of the biceps, was entering the substance of the long head. It had been severed by the missile, thereby depriving the muscle of its blood supply. No other artery entered the muscle.

This case is a good example of the complete death of a single muscle followed by early gas gangrene. I saw a similar case in the biceps in the North African campaign; but it is the only single muscle in which I have encountered complete destruction, and this is accounted for by the fact that it is supplied by a single artery.

Lower Limb

Cases of Main Arterial Damage

Seven cases of gas gangrene come under this heading. Five resulted from injury to the popliteal artery and two to injury of the dorsalis pedis. As the history is very similar in each case they will not be recorded in detail.

Injuries to the main blood vessels of the lower limb are a most potent cause of gas gangrene, and in my experience almost invariably result in amputation. In the series of 6,000 cases there were 9 in which the popliteal artery was injured; in every case amputation had to be performed. Out of four cases of ligature of the femoral artery three resulted in amputation. Should gas gangrene supervene in such cases it is very rapid, and often fatal within 24 hours on account of the vast area of muscle involved. When a main artery has been ligatured in the leg the patient should be watched hourly and amputation performed at the first sign of clostridial infection. Particularly dangerous is the case in which the femoral artery has been ligatured and there is an additional wound of the lower leg; in such a case primary amputation should be carried out. Severance of the anterior tibial artery is more prone to cause gas gangrene than the posterior tibial, for in the calf the peroneal artery can carry on the circulation. If the anterior tibial artery requires ligature its muscles below this point are ischaemic and should be removed.

The thigh is the most interesting site in the body for the study of gas gangrene, and an intimate knowledge of the vascular supply of the muscles is of paramount importance. The muscles of the upper part of the thigh are supplied by arteries emerging from the pelvis, and those of the lower thigh by the profunda femoris and its branches. Should the femoral artery be injured below the origin of the profunda femoris it is the lower leg which is temporarily deprived of its blood supply, and dry gangrene may ensue. The muscles of the thigh are unlikely to be involved by gas gangrene owing to their receiving a normal blood supply by way of the profunda femoris.

Wounds of the popliteal artery present a very different picture, for after ligature of the vessel the calf muscles exposed in the wound are avascular and gas gangrene is more likely to occur. Once clostridia gain an entry the spread down the leg muscles is only a matter of hours, and as large masses of muscle are involved the toxaemia is extreme and rapidly fatal. Exploratory incision of the popliteal fossa should therefore not extend further down the limb than is absolutely necessary. The larger the wound the more avascular muscle is exposed; it is a happy hunting-ground for micro-organisms, and the danger of gas gangrene is greatly enhanced.

The site at which the popliteal artery is ligatured is of considerable importance. If the injury is above the origin of the inferior geniculate arteries the collateral circulation may prove sufficient, but, should it be below, the collateral circulation is most precarious. Only two very insignificant arteries are available—the anterior and posterior tibial recurrent. Of these the latter is inconstant, while the former is very small and incapable in itself of establishing the collateral circulation.

A wounded soldier seldom comes to operation under six hours. By that time muscle necrosis is setting in if arterial damage is present. On approaching a wound of the popliteal artery one should first ascertain if the circulation below the knee is adequate. If the foot and leg are warm operation should be postponed, for interference with the artery may cause spasm, as illustrated by the following case:

Pte. C. sustained a shell wound of the posterior aspect of the knee on July 11, 1944. He was admitted to hospital the next day; there was a small haematoma in the calf. The foot was warm and the dorsalis pedis pulsating; injury to the popliteal artery was not suspected. On account of the swelling of the knee-joint it was thought advisable to explore the wound to ascertain if the joint had been penetrated. The wound was enlarged and the blood-clot was evacuated. The popliteal artery was found severed above the inferior geniculate arteries, and was ligatured. Pulsation in the dorsalis pedis ceased. Gas gangrene was present in the lower limb next day, and although amputation through the thigh was carried out the patient died. If the operation had been postponed until the collateral circulation was more fully developed the chances of survival of the limb and the patient would undoubtedly have been enhanced.

If the limb is cold and pulsation is absent in the dorsalis pedis, then treatment depends on whether the injury is above or below the inferior geniculate arteries. If it is above, then the probable explanation is arterial spasm. The wound should be explored and the damaged segment of the artery excised and the artery ligatured. On return to bed vasodilatation should be encouraged by hot drinks, heat to the uninjured limbs, and alcohol. Smoking, which has a vasoconstrictor action, should be forbidden. There should be no external pressure on the limb in the form of encircling plaster or bandage. The limb, if fractured, should rest on a Thomas splint with light traction. Heat is contraindicated; it increases oxygen demands, so hastens the onset of gangrene and favours the growth of pathogenic organisms. The limb should be exposed to the air or packed in ice. Should the injury be below the origin of the inferior geniculate arteries, then there is but one course—amputation of the limb.

The remaining two cases of injury to the main artery causing gas gangrene occurred in the dorsalis pedis, with much destruction of tissue; gas gangrene was present on the dorsum of the foot.

Injury to Muscular Branches

Damage to the smaller arteries and to those of individual muscles is particularly interesting and important in the thigh. The profunda femoris is the main source of supply to the muscles in this region. Its lateral circumflex branch supplies the greater part of the quadriceps; the main artery itself supplies the adductor and hamstring group of muscles. If either is injured muscle ischaemia will be extensive. This artery is liable to injury in fractures of the femur, especially when the bone is comminuted by a missile entering from the lateral side. In the great majority of compound fractures of the femur in war this artery escapes injury, so ischaemia will be limited to the torn and ragged muscle in the vicinity of the fracture, and gas gangrene is most unlikely to develop. If, on the other hand, the artery is injured high up in the thigh, the adductor and hamstring group of muscles are almost wholly deprived of their blood supply; in which case primary amputation should be performed, for gas gangrene is apt to be extensive and rapidly fatal. When the injury is lower in the thigh, more limited areas of muscle are involved and local excision may suffice. This artery is the key-note to gas gangrene in the thigh, and a thorough knowledge of its distribution is essential to successful surgery. In carrying out débridement of a wound it is important not to injure the profunda femoris or its branches;

when this occurs the patient returns to bed with a fresh mass of ischaemic muscle, in which gas gangrene is most likely to develop. There is nothing more disturbing to a surgeon than to find clostridial infection 48 hours after a well-done operation.

The seven cases of injury to muscular branches are of particular interest and will be recorded in detail; comments as to the vascular distribution will be made in each case. All underwent operation about the 24-hour period; and, as only localized areas of muscle were involved, generalized symptoms were not far advanced. They were diagnosed by the presence of clostridia and the typical "deadhouse" smell.

Gdsmn. D. was wounded on July 30, 1944, and admitted to hospital the next day with a wound in the buttock. Early gas gangrene was present in the upper part of the gluteus maximus; all gangrenous muscle was excised. The missile had pierced the muscle in the region of the greater sciatic foramen. During the operation the superior gluteal artery was sought for as it emerged from the pelvis; its superficial branch was found to have been severed.

The gluteus maximus is a large muscle and is supplied by several arteries. The superficial branch of the superior gluteal supplies the upper portion, the inferior gluteal the middle portion, and the lower part of the muscle is supplied by the first perforating branch of the profunda femoris and the medial circumflex arteries. The superficial branch of the superior gluteal artery having been severed in this case, the upper part of the muscle underwent necrosis, and gas gangrene resulted. If the missile had severed the superior gluteal artery gas gangrene would have been much more widespread. This artery is practically the sole supply to the gluteus medius and minimus, and both these muscles would have been involved. It is common knowledge that certain buttock wounds may result in serious gas gangrene, and I believe this is the explanation.

L/Cpl. E. was wounded by a shell fragment on July 10, 1944, and admitted to hospital next day. There was a large foul-smelling through-and-through wound in the upper thigh medial to the femur. On enlarging the wound an extensive amount of gangrenous muscle was found, involving the adductores brevis, longus, and magnus, also portions of the semitendinosus and semimembranosus; it was confined to the region of the mid-thigh. The profunda femoris artery was severed in the region of its second perforating branch. All necrotic muscle was removed.

Gnr. F. sustained multiple shell wounds of the left calf on July 14, 1944. On admission next day the calf was swollen and foul-smelling. On exploration of the wound the gastrocnemius was found to have been traversed by a missile from the lateral to the medial side and about 3 in. below the knee; muscle injury was extensive. The part of the muscle distal to the track was gangrenous. No particular arterial damage could be found, but one concludes that the sural arteries, as they run down in the substance of the muscle, must have been severed, thereby depriving the muscle beyond this point of its blood supply.

Prisoner of War G. was admitted on July 24, 1944, with an antero-posterior through-and-through wound of the mid-thigh lateral to the femur. On exploring the wound a mass of early gangrenous muscle was found, involving the middle third of the vastus lateralis and vastus intermedius, also a small portion of the lateral border of the rectus femoris. The track of the missile was in the vicinity of the descending branch of the lateral circumflex artery; this artery was sought for and found severed.

The vastus lateralis and vastus intermedius are supplied by three arteries—the upper third by the transverse branch of the lateral circumflex, the middle third by the descending branch of the lateral circumflex, and the lower third by the lateral superior geniculate arteries. The rectus femoris gets part of its blood supply from the descending branch of the lateral circumflex. In this case the descending branch of the lateral circumflex was severed near its origin, thereby depriving part of the above-mentioned muscles of their blood supply, and gas gangrene supervened.

Spr. H., admitted on July 18, 1944, was in similar case to the above, except that the descending branch of the lateral circumflex was injured lower down; the gangrenous area was thus far more limited.

Pte. I. was admitted on July 26, 1944, with multiple shell wounds of the posterior aspect of the thigh. On exploring the wound the semitendinosus was found gangrenous except at its upper end; all gangrenous muscle was removed.

The semitendinosus has a dual blood supply. The upper part is supplied by the medial circumflex, and the main body of the muscle by a branch of the second perforating artery. This artery divides into two branches—one supplies the semimembranosus and the other the semitendinosus. On removing the main body of the muscle this last artery was not located; it had evidently been severed by a missile.

Pte. J. was admitted on July 26, 1944, with multiple shell wounds of the left thigh; his case was similar to the above, but, in addition to the semitendinosus, the semimembranosus was also gangrenous. Both muscles were partially removed.

The semimembranosus, in addition to being supplied by a terminal branch of the second perforating artery, is also supplied by the third and fourth perforating arteries after they pierce the adductor magnus. The point where the second perforating artery divides into its terminal branches is very close to the third perforating artery as it emerges from the adductor magnus; so that a missile is very apt to injure both arteries, as occurred in this case.

Discussion

The distribution of clostridia is widespread. Cutler and Sandusky (1944) found the incidence of clostridial contamination in aerial warfare as great as that of land warfare and that of accidental civilian wounds. I have seen an Italian sailor come off a ship with well-established gas gangrene. The clostridia can be grown from the skin (Roberts, Johnson, and Bruckner, 1933) as well as from wool (Schenken, quoted by Mais, 1940). It can be grown almost without fail from the battle-dress. MacLennan (1943) states: "Their absence from war wounds is a matter of surprise rather than satisfaction; their presence, for resignation rather than alarm." There still exists a fallacious belief that direct contact with the soil is the chief causal factor in the establishment of gas gangrene; the Cutler and Sandusky findings must surely stamp this out for ever. It is the clothing that is the important vehicle, especially the battle-dress, which is largely composed of wool. Tropical kit, being made of cotton, does not harbour the clostridia to the same degree, and should there be an increase of gas gangrene in the European theatre of war in excess of the desert campaign this will probably be the explanation.

MacLennan has shown that in the desert warfare 30% of all wounds contained the organism of gas gangrene, yet only 1% of those so contaminated developed anaerobic myositis. Why is the percentage so small? The answer undoubtedly is that in only 0.33% of all wounds has arterial damage been inflicted and a sufficient amount of ischaemic muscle produced in which the clostridia can multiply.

We must resign ourselves to the fact that many war wounds are contaminated with clostridia, and that, provided ample necrotic muscle is present, gas gangrene will ensue. Early reports on penicillin would indicate that it is powerless to stem the progress. At present the elimination of gas gangrene can come only from early and efficient surgery, which can be greatly aided by a thorough knowledge of the blood supply of the muscles.

I am indebted to Col. T. F. Arnott, O.B.E., T.D., commanding a general hospital, for permission to publish this paper.

The Joint Consultative Council of institutions recognized by th Minister of Health for the training of health visitors, and of organizations of health visitors, has issued its report for the year 194 from 7, Victoria Street, London, S.W.1. The council, whose chairman is Prof. Winifred Cullis, D.Sc., originated in a conference o representatives of training institutions convened by the Wome Public Health Officers' Association in November, 1931, and wa formally constituted in January, 1932. During the last 14 years i has been a useful means of conveying the conclusions of its member to the Ministry of Health, the Royal Sanitary Institute, and othe bodies, on matters affecting the training and examination of healt visitors, and has been responsible for five publications based o independent inquiry. An inquiry into the alleged shortage of healt visitors in 1941 was conducted by the Joint Consultative Counci but the results were not published. Though the position has altere since then, there was in 1941 no acute or general shortage of healt visitors.

ARSENICAL ENCEPHALOPATHY

A NOTE ON THE CONDITION STRESSING THE VALUE OF POSTURAL TREATMENT, WITH CASE RECORDS

BY

G. A. RANSOME, M.R.C.P.
Lieut.-Col., I.A.M.C.

Capt., R.A.M.C.

AND

L. M. GUPTA
Capt., I.A.M.C.

During an 18-months period—April, 1943, to Sept., 1944—in an area where malaria is hyperendemic and its cerebral manifestations severe and often fatal, it was expedient for us to form a "coma team" analogous to Sir Leonard Rogers's cholera team. This team has treated, in a small ward equipped for the purpose, 155 cases of fully developed coma attributable to malaria in Indian other ranks and camp followers. In addition to malarial coma, cases of coma due to such causes as uraemia, cholaemia, etc., and on five occasions following the injection of arsenicals, have been seen. That these five patients recovered, while at the same time the majority of similar cases occurring in other units terminated fatally (Davies, 1944), is attributed by us to the use of postural treatment in nursing. Support for this assertion, though not conclusive, may be drawn from the fact that in another hospital five cases treated on orthodox lines ended fatally; a sixth case was seen by one of us (J. C. S. P.) some hours after the onset of coma with convulsions. This patient finally recovered on the adoption of the method of treatment outlined below.

Originally devised to prevent the onset of pulmonary oedema, so common in malarial coma, nursing these patients in the sitting posture not only was found to prevent the onset of pulmonary oedema but appeared significantly to modify the depth of coma and the final outcome. The rationale of this procedure is dealt with in the discussion. We will here give a brief description of the condition and our method of treatment.

Description of the Condition

Arsenical encephalopathy—synonyms of which are arsenical serous apoplexy (Lees, 1937), arsenical haemorrhagic encephalitis, and arsenical encephalorrhagia—has occurred in 1.3% of the patients treated for syphilis by the rapid five-day method of administration of mapharside, and has been found to occur in the Army, using neoarsphenamine, and particularly in Tamil patients, with sufficient frequency to merit the most serious attention of all medical officers.

The following description of the pathology is that of Kinnier Wilson (1940). Perusal of the recent literature, of current textbooks, and of fatal case-sheets has added but little to his account of the clinical and histological features.

> According to the English Salvarsan Committee's Report,[1] about 50% of "salvarsan deaths" in all countries have been due to a "haemorrhagic encephalitis," distinguished by abundant small perivascular effusions (mostly of the ring type), plugged capillaries with minute necrotic zones around them, and sometimes incomplete parietal occlusion in larger vessels; on occasions these thrombi are hyaline (Lissauer,[2] von Marschalko,[3] Scott and Moore[4]). Interstitial reactions otherwise (cellular infiltration of vessel coats rather than of perivascular spaces) are never pronounced and frequently lacking.
>
> Multiple minute capillary and pericapillary lesions of this kind, with hyaline thrombosis, are found also in carbon monoxide poisoning and narcosis, and were observed during the war in phosgene-gas cases. They occur, too, in cerebral malaria, fat embolism, and other disease conditions.
>
> Subpial extravasation may accompany the cerebral, which is often well seen in optic thalami, cornu Ammonis, tegmentum, pons, and elsewhere (Scott and Moore, Globus and Ginsburg,[5] Pollak and Riehl[6]). At times, however, nothing more than congestion and oedema is discovered (Obermiller,[7] Stuhmer[8]). Moderate demyelination round haemorrhagic zones was remarked by Strauss and Globus.[9]

Examination of the cerebrospinal fluid shows that initially the pressure is normal. Later, as secondary cerebral oedema sets in, the pressure tends to rise. This also occurs in cerebral malaria. Protein varies from 40 to 300 mg. per 100 c.cm. Globulin is increased, but less so than in infective conditions—e.g., acute anterior poliomyelitis. The cells are usually normal; rarely are there red blood cells.

Aetiology

The causal factor is unknown. Apparently it is (1) not related to the arsenic radical, since poisoning by inorganic arsenic does not give rise to cerebral symptoms (Halcrow, 1943); (2) not related to dosage (Anwyl-Davies, 1941) (nevertheless the high incidence in the rapid mapharside method of treatment must be kept in mind); (3) not due to the Jarisch-Herxheimer reaction, since arsenical encephalopathy has occurred in non-syphilitics (Lees, 1937; Glaser, Imerman, and Imerman, 1935).

There may be some relationship to arsenical purpura—the disintegration of the arsenobenzene compounds in the blood being a possible factor (Halcrow, 1943). Further investigation of this is required. The tourniquet test, bleeding time, and platelet counts should be done in all cases; the very few that we have done so far have been normal.

The fact that recent cases have been described as occurring during pregnancy (Tzanck and Lewi, 1939; Nelson, McGibbon, and Glyn-Hughes, 1943), and the high incidence in Tamils (Davies, 1944), suggest the possibility of a protein or other dietetic deficiency. The work of Vail (1941) on the increased sensitivity to arsenic in the presence of hypovitaminosis-C, and of Horne and Scarborough (1940) on the value of hesperidine (vitamin P) in the treatment of arsenical purpura, is of the greatest interest in this connexion.

Symptomatology

Signs and symptoms usually appear after 2 to 4 injections of the first course of treatment, and may be associated with irregularity in treatment. They begin 1 to 4 days after the last arsenical injection—commonly the second—when headache, vomiting, and delirium are succeeded by deepening coma, a rising temperature, and death. Focal lesions, such as Jacksonian fits, facial palsy, external and internal ophthalmoplegias, have all been observed, as has also a meningitic reaction, although rarely. In cases which recover there may be transient mental and bizarre neurological pictures. These normally pass off after a few days.

Relation of Symptoms to Lesions.—The stage of irritability, headache, fits, and nausea corresponds to the initial vascular lesions. Deepening coma and death appear to be due to acute reactive oedema of the brain.

The average mortality rate is 75% (Kinnier Wilson). In recent literature 34 cases have been described, with 25 deaths; the mortality rate in military practice seems to have approximated this figure.

Diagnosis

Diagnosis may be facilitated by checking the field service card (IAFM 1272), usually carried in the pay-book, and by looking for needle marks in arms and buttocks. Cases are sometimes mistaken for other forms of encephalitis, cerebral malaria, cerebrospinal meningitis, benign lymphocytic meningitis, poisoning by drugs, alcoholism, epilepsy, and hysteria. Of these, in view of the fact that cerebrospinal meningitis will be excluded by lumbar puncture, cerebral malaria is by far the most important, and if the patient comes from a malarious area he must always be rigorously treated for this, irrespective of whether the clinician thinks that the case is one of arsenical encephalopathy or not.

Arsenic and Malaria.—There is evidence to show that the organic arsenicals can reactivate latent malaria, and cases of cerebral malaria have been recorded in which there were negative blood slides and positive brain smears after arsenical administration (Castellani, Marinesco, and Draganesco; quoted by Anderson, 1927). One so-called case of "arsenical encephalitis" in this army, which received no antimalarial therapy, was proved later to have been malarial in origin.

Principles and Practice of Treatment

The principles of treatment are: (1) to prevent, so far as is possible, the onset of secondary cerebral oedema and exudation through damaged capillaries; (2) to inactivate circulating arsenical drugs; (3) to observe the principles of nursing coma cases; (4) to anticipate complications—e.g., hyperpyrexia, convulsions, pulmonary oedema, pneumonia; (5) in malarious areas and in patients who have returned from malarious areas, treatment must be as for cerebral malaria.

Oedema of the brain in the past has been successfully relieved by repeated lumbar punctures combined with venesection. In view of the fact that in the prone position venous and hence capillary pressures are 80 to 100 mm. of water, while in the sitting patient they are negative to atmospheric pressure, "decongestion" can be achieved simply by nursing the patient sitting up, using a back-rest. The cerebrospinal-fluid pressure at ventricular level then drops to atmospheric level or less.

Postural nursing is the greatest single factor in saving life, and should be used in every case from the onset.

Lumbar puncture should be done initially for diagnostic purposes and the pressure, if raised, reduced to 100 mm. of water. This should be repeated if in spite of postural nursing the coma appears to deepen. A cisternal puncture is often more convenient.

Dehydration of the brain is indicated only if the coma is deepening in spite of postural nursing and lumbar punctures. It is done as for head injuries: (i) Concentrated serum albumin, 25% solution intravenously (U.S. Naval package: 25 g., equal to 450 c.cm. of plasma), is the method of choice. (ii) Failing the above, concentrated glucose-saline as supplied by the Army, 60 to 120 c.cm. intravenously, or hypertonic glucose solution (or sucrose, if available) by slow drip infusion.

Sodium or calcium thiosulphate given intravenously in 0.5-g. doses once or twice daily is of doubtful value. Calcium gluconate and vitamin C may influence capillary permeability. Adrenaline is of doubtful value. Drugs for the purpose of detoxicating the organic arsenicals—the experimental work on which was reviewed in an editorial in the *Journal* (1943, **2**, 681)—have not been used by us, but to be of value they would have to be employed early in the disease process. This is not always feasible, since many of the patients are first seen after coma has developed; but the method might have been applied with advantage to our Case 3.

Complications.—Pulmonary oedema is largely avoided by posture. *Hyperpyrexia* is anticipated by routine rectal temperatures and dealt with by tepid sponging and fanning. *Convulsions and restlessness* should receive ruthless treatment. For fits, hexobarbitone sodium followed by paraldehyde by mouth, or sodium phenobarbitone 6 gr. intramuscularly, is indicated. It cannot be stressed too strongly that patients should not be allowed to have fits, because they raise the cerebral capillary pressure in capillaries whose endothelium has already been damaged. *Adequate antimalaria therapy* should be given, as outlined in the "Blue Book" for pernicious cases.

Summary of Treatment.—(1) Examination of the patient. (2) Lumbar puncture. (3) Sit the patient up on a back-rest. (4) Treatment of complications—e.g., pulmonary oedema, fits, hyperpyrexia, etc. (5) Adequate antimalaria therapy. (6) Calcium or sodium thiosulphate i.v., 0.5 g., with calcium gluconate and vitamin C if available (of doubtful value). (7) Adequate hydration and nutrition by transnasal intragastric Ryle tube left *in situ*.

Case Notes

Case 1.—An Indian sepoy, aged 25, was admitted to hospital on the evening of March 31, 1944, deeply unconscious: 1½ hours before admission he had felt giddy and had fallen down unconscious, bringing up blood-stained frothy sputum. On March 5 he had a sore on the penis, and dark-field examination showed *T. pallidum*. Treatment had consisted of three injections of N.A.B. and bismuth, the last injection having been given on March 27. On admission he was in deep coma, responding only to painful stimuli, with stertorous breathing and frothing at the mouth (not blood-stained). The eyes were half opened, with a vacant stare. The general attitude was that of midbrain posture, arms adducted and flexed across the trunk, elbows and wrists flexed and supinated, fingers semiflexed, and lower extremities extended at all joints. There were tonic spasms lasting two to three minutes, associated with stertor, trismus, some opisthotonos, ocular deviation to the right, and an accentuation of the position, described above. During the resting phase, of similar duration, the arms were often extended and athetoid movements of the fingers were present. A sucking reflex was also elicited at this stage. Just before the height of the tonic phase, flexion of the head to one side produced relaxation of the contralateral limb (Magnus and de Kleijn reflex). Grasp reflex absent; deep reflexes all present and exaggerated; ankle clonus present; plantars extensor and abdominals abolished. Muscle tone appeared normal, as did crude position sense. Conjunctival and pupillary reflexes and swallowing reflex present. C.S.F.: Cells less than 10/c.mm.; proteins, 60 mg./100 c.cm.; chlorides, 720 mg./100 c.cm.; sugar, normal; pressure, no increase. W.B.C., 11,600/c.mm.—polymorphs 54%, lymphocytes 44%, monocytes 2%. Treatment was as described above. April 1: Still in deep coma; urinary incontinence; temperature rose in the evening to 104° F. April 2: Coma lighter; patient easily roused by questioning; plantar reflexes became flexor. April 3: Conscious; B.P. 136/74; still incontinent. April 4: No incontinence. Recovery uneventful.

Case 2.—A Sikh, aged 19, was admitted to hospital on April 15, 1944, deeply unconscious. Five days previously he had received the third injection of N.A.B. for sero-positive syphilis. He was very restless on admission, but when still, lay on his back in a position similar to that of Case 1. There was increased tone in all the limbs, with a tendency to spasmodic arching of the trunk, when the neck became rigid. During the intervals between the spasms the neck was so relaxed as to enable the chin to touch the chest wall. Kernig's sign was negative. Superficial reflexes all present; abdominals brisk; deep reflexes exaggerated and equal on both sides. Spontaneous jaw clonus; no ankle-clonus; plantars flexor. Pupils slightly dilated and eccentric; reaction to light sluggish. No facial paralysis. Respirations regular, rapid, rattling. No cyanosis. No engorgement of veins. Skin: secondary rash present. Healed scar on penis. Pulse 140/min.; B.P. 139/70; rectal temperature 103.2° F. Following treatment he became conscious 42 hours after admission. For the next few days his cerebration was slow but speech was unaffected. Improvement was rapid, and he was discharged for further convalescence on May 5.

Case 3.—A Tamil pioneer, aged 20, was admitted to the V.D. ward on June 6, 1944, suffering from balanitis and penile sores. Two days later dark-field examination revealed *T. pallidum*. Anti-syphilitic treatment was given as follows:

June 15: N.A.B., 0.3 g.; bismuth, 0.1 g
„ 19: N.A.B., 0.3 g.; bismuth, 0.2 g.
„ 22: N.A.B., 0.45 g.
„ 26: Bismuth, 0.2 g.

On June 26 he complained of headache and had slight fever, so no arsenic was given. A blood film showed no malaria parasites. He made no complaint in the evening, and remained well during the next day, although his temperature in the evening rose to 99.4° F. On June 28 he was well early in the morning, but at 11 a.m. suddenly developed a rigor with twitching, and by midday was in deep coma, responding only to noxa. Temperature 102° F.; pulse 144/min.; respirations 18/min. Pupils were dilated, reacting sluggishly to light. No neck rigidity. Deep reflexes all present but sluggish. Conjunctival, abdominal, and cremasteric reflexes abolished. Plantars indefinite. Heart, lungs, and abdomen: N.A.D. No fullness of neck veins. Urine normal. C.S.F.: Pressure, 135 mm. of water; clear; cells 4/c.mm.; protein, 40 mg./100 c.cm.; chlorides, 750 mg./100 c.cm.; sugar, normal. Treatment on the lines described was started, and on the following morning the patient was drowsy, but responded to touch and to questioning. On June 30 he was fully conscious, and thereafter recovery was uneventful.

Case 4.—A Tamil pioneer, aged 22, was admitted to hospital on June 16, 1944, at 11.00 hours, unconscious and having fits. His history was that he had suddenly become unconscious at 10.00 hours. On June 2 sores appeared on the penis. Dark-field examination showed *T. pallidum*, and treatment, with N.A.B., was as follows: June 5, 0.3 g.; June 8, 0.3 g.; June 12, 0.45 g. Temperature on admission was 99.2° F.; pulse 96/min.; respirations 24/min. The patient was lying on his back with his lower extremities extended, and frequently rolled over on his side with his legs drawn up. His arms were moving about in front as if he was trying to grasp some object. Pupils dilated, equal, and reacted sluggishly to light. Consensual reflexes present. There was photophobia. Deep reflexes present; abdominals lost; plantars extensor; and ankle clonus present. Nothing abnormal in heart, lungs, and abdomen. C.S.F.: Pressure, 120 mm. of water; clear; cells less than 10/c.mm.; protein, 300 mg./100 c.cm.; chlorides, 600 mg./100 c.cm. Urine, normal. W.B.C., 8,000/c.mm.—polymorphs 77%, lymphocytes 21%, monocytes 2%. Treatment was given on the above lines, and on the morning of June 17 he was still deeply comatose, responding only to painful stimuli, though the depth of coma lightened towards midday. On the 18th the depth of coma was variable, and the patient became fully conscious the next day. Temperature became normal on June 21, and thereafter the patient remained well, without nervous residua.

Case 5.—A Central Provinces pioneer, aged 18, was transferred from the V.D. Dept. on Sept. 1, 1944. He was a case of seropositive syphilis, and had received treatment as follows:

Aug. 19: N.A.B., 0.3 g.; bismuth, 0.1 g.
„ 21: N.A.B., 0.15 g.; bismuth, 0.2 g.
„ 24: N.A.B., 0.3 g.
„ 28: N.A.B., 0.15 g.; bismuth, 0.2 g.
„ 31: N.A.B., 0.15 g.

On transfer the patient was in coma, with the eyes wide open and face congested. There were spontaneous movements of both upper limbs. No neck rigidity. Pupils were equal, central, and reacting to light. Fundus examination showed blurring of the disks, more marked on the left, with congestion of the veins. Deep reflexes present; superficial reflexes absent; ankle clonus present; plantars flexor. There was a macular rash all over the body. Temperature 101.8° F. Heart, lungs, and abdomen: N.A.D. C.S.F.: Pressure, 70 mm. of water; fluid clear; chemically normal. W.B.C., 5,600/c.mm.—polymorphs 75%, lymphocytes 24%, monocytes *nil*, eosinophils 1%. Treatment was given as in the previous cases, and on the following day (Sept. 2) he was still in coma. Plantars indefinite. In the evening the patient became irritable and resented examination. The plantars became extensor. On Sept. 3 he was conscious but dazed. He answered to his name, but still resented examination. Plantars flexor. On Sept. 4 the patient was fully conscious, and thereafter convalescence proceeded normally.

Discussion

In view of the fact that once capillaries are damaged exudation into the surrounding brain substance is likely to occur, earlier writers (Lees, 1937; Harrison, 1937) have advocated venesection (to reduce congestion), dehydration with hypertonic saline solutions, and lumbar puncture. Cerebral oedema undoubtedly does occur, and is of the interstitial type accompanying head injuries; it is not necessarily associated with a raised intracranial pressure, provided there is free cerebrospinal-fluid absorption. This type of oedema occurs in cerebral contusion and malarial and other encephalopathies.

Cobb (1936) has clearly outlined the physiological mechanism of the cerebral circulation, and notes the following points:

Hydrostatic Factor.—"There is a falling gradient of pressure from artery to vein, steepest in that part of the curve which represents the arteriole. Changes in arterial pressure have very little immediate and direct effect upon capillary and venous pressure, whereas changes in venous pressure affect capillary pressure immediately and conspicuously; in fact, venous and capillary pressures change equally and synchronously."

Osmotic Factor.—"The capillary wall, being a semipermeable membrane . . . is permeable to all the important osmotically active dissolved substances of the blood except protein, so normally plasma protein tends to prevent movement of fluid out of the vessels. In the arterial capillary bed the hydrostatic pressure is greater than the opposing osmotic pressure of the plasma proteins. Therefore a protein-free fluid is filtered into the tissue spaces. On the venous side of the capillary bed, moreover, the hydrostatic pressure is less than the osmotic pressure of the plasma proteins, and the fluid is reabsorbed. . . . . Any obstruction to venous flow, however, will raise the venous and capillary pressure to levels well above the osmotic pressure of the plasma proteins. Filtration from the plasma to tissue spaces will now take place throughout the capillary bed, whereas no real absorption into capillaries is possible; oedema results."

Effects of Posture.—(1) In the horizontal position the venous pressure measures 8 to 15 cm. of water. In the sitting position the cerebral venous pressure becomes negative to atmospheric pressure. (2) In the horizontal position the C.S.F. pressure is roughly equal throughout the ventriculo-subarachnoid system (100 to 160 mm. of water). In the sitting position the intracranial pressure becomes negative to atmospheric pressure, while the pressure in the lumbar sac nearly doubles.

The following table is an attempt to show what we conceive will happen on sitting the patient up; theoretically, the sitting posture should tend to prevent the onset of cerebral oedema (cf., elevation of a traumatized limb to prevent swelling).

Posture	Osmotic Pressure of the Plasma Proteins (mm. Hg)	Venous Capillary Pressure (mm. Hg)	Mean Reabsorption Pressure (mm. Hg)
Horizontal ..	25	12	13
Sitting	25	Approximates nil	Approximates 25

Finally, in presenting these cases as arsenical encephalopathy, the criticism may be levelled that they were in reality cases of cerebral malaria. That such may be so cannot be entirely refuted, since we have seen in the past undoubted cases of cerebral malaria with negative blood slides but with positive brain smears.

However, that five should have occurred is more than a coincidence, and we believe these to have been of arsenical origin rather than malarial. It is most unusual, with three-hourly thick blood films and an expert microscopist, to fail to demonstrate parasites in a true cerebral malaria.

The value of the sitting posture in nursing these coma cases is in no way diminished, since this is the method applied by us with success in the treatment of malarial coma and of the coma of heat-stroke, and we hope that others will apply it to arsenical encephalopathy occurring in an area where malaria is not hyperendemic.

Summary

A brief description of arsenical encephalopathy is given and five cases are described.

That these five patients survived is attributed to the procedure of nursing cases in the sitting position.

The method of treatment is described and the physiology of the procedure discussed.

We wish to express our thanks to Col. F. R. Cawthorn, I.A.M.C., who, having early appreciated the value of a "team," kept its members together despite many difficulties; and to Major R. I. Krishnaswami, I.A.M.C., for help and criticism in the preparation of the paper. Our thanks are also due to the nursing officers, Miss D. J. Oliver and Miss J. St. John Inman, whose untiring efforts have contributed in no small measure to the successful treatment of these cases

PROLAPSE OF THE RECTUM IN WOMEN*

BY THE LATE

HAROLD CHAPPLE, M.Ch., F.R.C.S., F.R.C.O.G.

Senior Gynaecologist to Guy's Hospital

Apparently it is not generally realized that prolapse of the rectum in women can be treated successfully by an abdominal operation. Nevertheless this is so, and I hope the following account will demonstrate that the method here described should be included in the armamentarium of those surgeons who have to decide the treatment of patients unfortunate enough to suffer from this distressing complaint.

The operation is one that should not be difficult in the hands of those who are accustomed to operate low down in the pelvis, and its guiding principle is self-evident. The desirability of "hooking it up from inside" must have occurred to surgeons, but I acknowledge my indebtedness to Victor Bonney—to whom, incidentally, gynaecological surgeons owe so much—for information as to whether this was or was not a practical proposition. In his book on operative gynaecology he has given a brief account of such an operation, and this can be consulted with advantage by those sufficiently interested.

A war widow aged 29 consulted me on the advice of a colleague of mine because of a prolapse that had occurred shortly after the birth of her first child, which had taken place five years previously. On examination I found that the prolapse was rectal and that some 4½ to 5 inches of bowel protruded. The tone of the anal sphincters was noticeably weak, and pelvic examination showed that the uterus and pelvic floor were relaxed and rather lower than normal. For the relief of this condition she had been operated on by a surgeon who had excised the protruding rectal wall from below in the manner accepted to be adequate, but this had not relieved the condition for long. Knowing the work of this surgeon, who was once a resident of mine, I am sure the operation had been well and truly done and that the failure was in the design of the operation and not in his execution of it. She then consulted a well-known proctologist, and his decision was given against further operation, but electrical treatment was instituted and some pararectal injections were made. Unfortunately no relief followed a persistent course of this treatment, and she was informed that now nothing could be done except a colostomy. This in a young woman of her mentality offered a grim choice from which she naturally shrank.

---

* The manuscript of this paper was received from the author on the day before he died.

The patient now became desperate, both mentally and physically, as her whole life centred round the avoidance of calamities in which the bowel contents were suddenly voided. So I decided to operate on her by the abdominal route, having noted that she was a young and attractive woman and would probably wish to marry again. She was realist enough to know that it was the cure of the prolapse that was the target, and if during the course of the operation it should prove to be essential to take steps that would make future pregnancy undesirable that must be regarded as of secondary importance. To me, as the operator, this decision of hers was vital, as I should have to decide during the course of the operation whether to ligature the Fallopian tubes or not. If I were forced to attach the bowel on to the body of the uterus to give it adequate support a subsequent pregnancy might lead to disaster, and must therefore be rendered impossible.

Operation.—With the patient in the Trendelenburg position a lower median incision was made of length adequate to permit free access to the pelvis. The pelvic bowel and rectum were drawn up and a series of No. 2 silk stitches put in place so as to obliterate the pouch of Douglas and suspend the bowel to the floor and the posterior aspect of the vaginal wall. I found the use of Lane's cleft-palate needle-holder a great help in placing these deep and important stitches accurately. Taking care of course not to perforate the bowel, several more tiers were then superadded and the anterior aspect of the bowel supported on to the upper part of the posterior wall of the vagina and the lower third of the cervix, with precautions against leaving a peritoneal pocket into which small intestine could prolapse. Thus far the bowel was nicely and firmly held, and on pulling up the uterus to the position which it would occupy later when suspended, all seemed well, and so I decided against sterilization in this case, as it had not been necessary to attach the bowel to the body of the uterus, which would therefore be unaffected if it were ever subsequently enlarged by a pregnancy. In order to avoid any likelihood of leaving a possible source of obstruction by looping, the pelvic bowel was further spread out and attached to the posterior aspect of the left broad ligament and out on to the pelvic wall, of course avoiding the left Fallopian tube and ureter. On being satisfied on that count, the uterus was firmly suspended by pleating the round ligament on either side from the uterine body out to the pelvic wall. The ends of these silk sutures were then drawn out through the sheath of the rectus on either side and sewn into it firmly. This gave a firm support. (Let me mention here that if it had worked out to be necessary to fasten the bowel on to the back of the uterine body to get adequate support I should have ligatured the Fallopian tubes and fixed the uterus into the abdominal incision by silk sutures.) The abdomen was closed, and on examination at the end of the operation the rectum was found to be very satisfactorily supported. The chief points in the after-treatment were to leave the bowel alone for seven days, and after that an easy and adequate action was produced by liquid paraffin and a small glycerin enema. A residue-free diet was given during these days.

Comment

I have waited for six months before making this report, and the result is so far excellent, and I can see no reason why it should not continue to be so. The bowel now acts readily with daily liquid paraffin, and the patient's evident happiness at the result of the operation is easily understood. Should she marry again later and become pregnant, and should I have to make the decision as to the method of delivery of the child, I should certainly advise Caesarean section and take no risk of any recurrence of her previous very undesirable condition. To this she readily assents, knowing what a recurrence of that condition would entail.

J. K. David and A. S. Minot (*Amer. J. Dis. Child.*, 1944, **64**, 327) record a case of recurrent haemolytic anaemia in a male infant aged 4½ months. Haemolytic activity of the patient's serum took place during an acute haemolytic crisis. After splenectomy the haemolytic activity was no longer demonstrable in the patient's serum and recovery followed.

TUBERCULOSIS OF THE LOWER LOBE

BY

RAYMOND C. COHEN, M.D., D.P.H.

Deputy Medical Superintendent, and Physician to Pulmonary Tuberculosis Unit, Essex County Council Hospital, Black Notley

Pulmonary tuberculosis as it affects the lower lobes has certain characters which deserve special consideration, and it is the object of this paper to call attention to the special features of treatment and prognosis of tuberculous disease in this situation. I have reviewed the clinical records of 2,200 cases of pulmonary tuberculosis in adolescent and adult women who have been treated in the sanatorium at Black Notley in the nine years 1935–43, abstracting those in which the disease was solely or predominantly affecting the lower lobe on one side. Only 81 such cases (3.68%) were found. Cases of tuberculous bronchiectasis—e.g., secondary to childhood bronchial obstruction by enlarged glands and subsequent atelectasis—and cases in which the disease had invaded the lower lobe by bronchogenic spread from one of the upper lobes, were excluded.

The low incidence of lower-lobe disease is striking. The incidence on the two sides did not show any significant difference (48 on the right, 33 on the left side). In 34 (42%) of the cases the apex of the lower lobe was affected, and 32 of these had progressed to cavitation by the time they came under supervision. This tendency to early cavitation of tuberculosis in the apex of the lower lobe is notable, and is worth bearing in mind when considering treatment.

In order to assess the results of treatment the 81 cases of lower-lobe disease have been divided into three groups, based on radiological appearances:—Group I (21 cases): Those showing tuberculous infiltration, including diseases of exudative type, but excluding those in which there was demonstrable cavity formation. Group II (28 cases): Those showing cavity formation, but excluding those in which the cavity occurred at the apex of the lobe. Group III (32 cases): Those in which a cavity had formed at the apex of the lower lobe.

The following is a review of the treatment given. Where pneumothorax is referred to it may be taken to include thoracoscopy, and division of adhesions whenever practicable.

Of the Group I cases, 16 were treated by an initial period of bed-rest alone, which secured quiescence of the disease in 11; an artificial pneumothorax was induced in 4 of the resistant cases and quiescence ultimately secured, though one required a phrenic avulsion in support of the pneumothorax. Of the remaining cases, 3 were successfully treated by early induction of a pneumothorax, 1 by a phrenic avulsion, and 1 by intravenous gold.

Of the Group II cases, 4 were treated by an initial period of bed-rest, which succeeded in 2; one of the remainder was successfully treated by pneumothorax. Of 13 cases treated by early pneumothorax, 10 succeeded, 1 was successful when reinforced by a phrenic avulsion, and 2 were abandoned owing to rapid spread of the disease. Phrenic paralysis alone succeeded in 7 out of 10 cases, the 3 failures subsequently becoming quiescent after treatment by pneumothorax. One case in this group retrogressed in spite of a phrenic avulsion combined with intravenous gold therapy and followed by pneumothorax.

Of the Group III cases, 10 in which the apical cavity was small were treated by bed-rest alone, 8 successfully. Of 16 cases treated by artificial pneumothorax, complete quiescence was secured in 12, 1 had to be reinforced by a phrenic paralysis, and 3 failed entirely. Five cases were treated by early phrenic paralysis—3 succeeded and 2 failed. One other case became quiescent after a course of intravenous gold, but the relative importance of the gold and the concomitant bed-rest was uncertain.

Treatment by Pneumoperitoneum

The use of pneumoperitoneum in the treatment of pulmonary tuberculosis has added another weapon to our armamentarium which most tuberculosis workers agree is of real value in selected cases. One of the indications seems to be disease of the middle and lower lobes, and subsequent to the series of cases reviewed in this paper I have treated a number of cases of mid- and lower-lobe disease by phrenic paralysis followed by pneumoperitoneum. The results so far have been very successful, particularly with middle-lobe cavities and cavities in the middle or periphery of the lower lobe. For the treatment of cavities in the apex of the lower lobe the efficiency of pneumoperitoneum is not so clear.

Prognosis

The prognosis of tuberculosis of the lower lobe has generally been regarded as poor, but it seems that this is an unjustifiably gloomy view to take. In cases without cavity formation (Group I) the prognosis with suitable treatment appears to be good, as the only unsuccessful case in the present series was that of a patient who discharged herself before treatment was completed. In Group II also, quiescence was ultimately secured in 25 out of 28 cases, and the prognosis is apparently good, though more active measures may be required for treatment than in Group I. Where the cavity affects the apex of the lower lobe, however, the outlook is not so favourable (Group III, 25 cases becoming quiescent out of 32—a "failure-rate" of 21.9%). There was a lower proportion of successful pneumothorax cases in this group. The probable explanation of this is that when the lung is collapsed the apex of the lower lobe moves into the paravertebral gutter and escapes compression.

Discussion and Conclusions

While it cannot be claimed that the figures quoted in this series are statistically significant, they represent the experience of a large sanatorium over a period of nine years, and it is probably justifiable to draw certain conclusions based on clinical observation of these cases. These conclusions are:

1. The incidence of lower-lobe tuberculosis is low (3.68%) in a series of 2,200 cases of pulmonary tuberculosis in adolescent and adult women.
2. There is a distinct tendency to early cavity-formation.
3. The immediate prognosis with adequate treatment is better than has usually been thought.
4. If a cavity has formed by the time the patient comes under treatment it is not wise to rely on too long a period of bed-rest alone, and more active treatment should be given as soon as the patient is clinically fit for it.
5. For cavities not at the apex of the lower lobe a phrenic crush followed by pneumoperitoneum offers a good chance of success, and is probably the best initial treatment. Artificial pneumothorax should be held in reserve for these cases, however, and if the cavity is not showing signs of closure after two months the pneumoperitoneum is unlikely to succeed, and pneumothorax should be attempted.
6. Where the cavity is at the apex of the lower lobe an initial pneumothorax seems to be the best treatment. I have not yet had enough experience of phrenic paralysis followed by pneumoperitoneum in cases of this group to express an opinion whether such treatment will overcome the difficulty of the apex of the lower lobe retreating into the paravertebral gutter when collapse therapy is applied to the lung. It seems unlikely that elevation of the diaphragm, even to the height which can be secured when phrenic paralysis is reinforced by pneumoperitoneum, will have more influence on the apex of the lower lobe than pneumothorax followed by adhesion section. At the same time, if a pneumothorax fails to secure complete closure of the cavity, elevation of the diaphragm may tip the scales in the patient's favour by providing a little extra relaxation to the lung, or possibly, in some cases, by "unkinking" a bronchus which had been partially obstructed and maintaining a retention cavity.

My thanks are due to Dr. W. A. Bullough, County Medical Officer, and Dr. M. C. Wilkinson, medical superintendent, for permission to publish the results.

As a war memorial to children killed by enemy action in London a beautiful and up-to-date children's ward is planned for St. Thomas's Hospital. During the air raids on London there were 12 direct hits on the hospital by high-explosive bombs and 2 by flying bombs, in addition to the fall of a large number of incendiaries. St. Thomas's carried on, caring at the same time for the many people brought in as casualties from incidents in the neighbourhood of the hospital. In September, 1940, two house-surgeons, three nurses, and four masseuses were killed by enemy action. There were no casualties among the patients during the raids.

PREVENTION OF MIGRAINE BY ORAL ADMINISTRATION OF CARBACHOL

AN ANALYSIS OF 12 CASES

BY

ALASTAIR KER JAMES, M.B., Ch.B.

It is now generally accepted that the immediate cause of the symptoms of migraine is spasm and distension of the cerebral arteries, particularly those of the scalp and the dura mater; and Rowbotham (1942) summed up the evidence in favour of this view. Many years ago other observers (Féré, 1883; Flatau, 1912) noted vascular changes during the course of attacks of migraine.

In view of this evidence it seems curious that there appears to be no record of any attempt to treat migraine by the administration of a parasympatheticotonic; but it was clinical observation and not therapeutic theory which encouraged me to follow up the unexpected results in Case 1, in which an attempt to remedy obstinate constipation due to an enormously dilated and elongated colon resulted in a marked improvement in migrainous attacks without much alteration in the bowel action. This was effected by giving one tablet of moryl—a proprietary preparation containing 0.002 g. of carbaminoylcholine chloride (carbachol *B.P.*)—thrice daily, but the patient later received twice that amount. The preparation named has been used throughout this experiment; the word "tablet" signifies a dose of 0.002 g. of carbachol.

Further cases of migraine were similarly treated as they arose, and the results seem to merit publication. Though the series is admittedly small, improvement has been consistent, the method is easy and inexpensive, and no alteration in diet or mode of living has been made. All the cases tabulated suffered from the classical symptoms of migraine—viz., periodic attacks of severe headache, often unilateral, generally preceded by visual disturbance, and always followed by vomiting or severe nausea, after which recovery ensued more or less rapidly.

Case 1 suffers from the colonic abnormality previously noted. Case 4 has pulmonary tuberculosis. No. 2 died of periarteritis nodosa three months after treatment by carbachol was begun. The remainder of the patients are in normal health. Some of the series have been taking carbachol continuously for many months, and no toxic symptoms have been observed apart from an occasional mild sensation of heat in No. 8, who takes six tablets daily.

Tabulated Summary of Results

Case	Age and Sex	Duration of Disease (Years)	Average No. of Attacks per Month			Daily Dosage of Carbachol (g.)	Duration of Carbachol Treatment (Months)
			With No Treatment	With Ordinary Treatment	With Carbachol		
1	56 F	46	—	1·5	0·75	0·012	33
2	56 M (1937)	45	10	8	4	0·006	3
3	33 M	4	4	1·2	0·75	0·006	28
4	37 F	9	1	—	very mild 0·16	0·004	20
5	19 F	5	10	4	0·2	0·008	11
6	14 M	7	12	4	0	0·006	6
7	36 F	22	8	—	0	0·006	9
8	52 M	12	10	4	1·25	0·012	11
9	44 F	30	3	—	0·3	0·004	7
10	29 F	15	3	—	0·4	0·006	7
11	23 F	4	2	—	0·4	0·006	5
12	24 F	5	8	—	1	0·006	2

The results are consistent and better than those of the commonly used remedies, and the beneficial effect is similar to that obtained in epilepsy by phenobarbitone. Sufficient time has not yet elapsed to form any conclusions whether the improvement remains permanent after discontinuing the drug. It seems probable that the oral administration of carbachol produces a less intense but more prolonged effect than injection. Cases in which migraine persists after the age of 50 seem to require larger dosage. It was further noted that the systolic blood pressure in the older age groups was low—average 124—which, together with the fact that in three cases known to me the attacks of migraine gradually ceased with the gradual increase in systolic blood pressure, suggests that only soft and elastic arteries can be affected by pathological spasm sufficient to produce migraine.

Further investigation into the efficacy of the method described can best be carried out by the general practitioner, who has the opportunity of closely observing his cases. It should thus soon be possible accurately to assess the value of this treatment.

Medical Memoranda

Gangrene of the Rectum as a Complication of an Enema

From time to time cases are recorded of injuries to the anus and rectum associated with the giving of enemata by means of the Higginson syringe. Such cases are not common, but the case reported below will serve to remind medical men and nurses of the serious consequences, sometimes fatal, which may follow this simple procedure. Gabriel (1937) and Bacon (1938) state that this accident occurs more commonly than is often supposed, and may pass unnoticed if the trauma is not very severe and the resulting pain not marked, and the condition is not reported to the medical attendant.

Case Record

A Polish miner, aged 49, was admitted to the French Hospital under Dr. Andrew Morland, on July 19, 1944, for severe melaena of four days' duration. There was a history of gastric ulcer with recurring attacks of symptoms going back eight years. On one occasion perforation had occurred; on two others haematemesis had been the outstanding symptom. The patient's condition was not very good: pulse 84 a minute but weak; temperature 98° F.; B.P. 100/80. Blood count: red cells, 1,600,000; leucocytes 4,600; Hb (Sahli) 30%. Urine normal. There was nothing else of importance to record.

On the fifth day after admission the patient complained of abdominal pain, and, next day, of soreness in the anal region. Temperature 99–100° F. He was found to have a foul-smelling purulent discharge from the anus, with swelling and redness of the surrounding skin. Proctoscopic examination revealed, however, that the whole of the right side of the rectum from the midline posteriorly to well above the midline anteriorly was a grey and sloughing mass; above and on the borders of the slough the mucosa was red and oedematous. The abdomen was tender in the hypogastric region, and slightly distended but not rigid. Temperature 100° F.; pulse 92.

It was learnt that three days previously a soap-and-water enema had been given, and was repeated the next day. The enema was given by a very efficient Sister by means of the Higginson syringe to which a rectal tube had been adapted, the patient lying on his left side. After the second enema he felt a pain, which did not last long enough for him to mention it.

It was considered that the patient's condition was serious, so Mr. H. W. S. Wright was asked to see him. He made an examination together with Mr. E. T. C. Milligan. In the meantime the temperature rose to 101° F.; the pulse was 92, and the patient complained of pain. A second proctoscopic examination was done. Diagnosis of gangrene of the rectum was made. A biopsy from the part above the slough was taken, which subsequently showed on section a polypoid mucosa without malignancy.

It was decided to treat the patient conservatively by giving him sulphathiazole and gas-gangrene antitoxin. Sulphathiazole 2 g. was given immediately, being followed by 1 g. every four hours for four days, then 1 g. every six hours for another six days. Antitoxin, 60 c.cm., was injected intramuscularly the first day, then 20 c.cm. for six days. Under this treatment the patient improved rapidly. Temperature and pulse were normal on the fifth day; the pain had disappeared; a slough was passed, leaving a clean ulcerated area which was healing satisfactorily; there was scarcely any discharge, and on August 15 only a small ulcer was present at the ano-rectal junction. At the patient's departure from the hospital on Sept. 6 this ulcer was completely healed, leaving no stricture.

Comment

The case just described is similar in many features to those of Rayner (1932), Pinnock (1937), Murray (1937), and Gabriel (1937). The only difference noted was, whereas in the previous cases the lesion was due to the hard nozzle of the syringe, in the present case it was the rectal tube, generally advised to be used, which produced the lesion. On the other hand, the rectal mucosa presented on section a polypoid appearance—a condition easily damaged even by slight trauma. The mechanism of infection is thought to be as follows: soap-and-water, which may contain caustic soda or potash, is injected under a certain pressure into the submucous layers of the anal canal and rectum, stripping off the mucosa and so depriving it of its blood supply. Micro-organisms usually present in this region find, therefore, a medium favourable to their development and spread.

The prognosis of such cases is always very serious, and death is a frequent end-result even after extensive surgical intervention. Pinnock had two cases with one death, Murray three cases with two deaths, and Gabriel three cases with two deaths. The treatment usually adopted consists of laparotomy with either colostomy or caecostomy. The results are not always satisfactory, the patient being sometimes left with a permanent colostomy or stricture of the rectum. The rapid improvement noticed in the case described was thought to have been due to the combined action of sulphathiazole and antitoxin. The sulphonamides provide us with powerful weapons to fight the high mortality of this serious accident.

I am indebted to Dr. H. S. Stannus for his advice, and to Mr. Wright and Mr Milligan for their proctoscopic findings.

A Case of Broncho-oesophageal Fistula with No Pulmonary Symptom

Broncho- or tracheo-oesophageal fistula is a well-known complication of erosive conditions of the oesophagus and is often found as an end-result of malignant adhesive peri-oesophagitis. The development of a direct opening between the oesophagus and the upper part of the bronchial tree might well be expected to bring about obvious signs of respiratory distress on the swallowing of fluids, but that this does not necessarily happen is apparent from the following clinical note.

Case Report

A man aged 60 was referred to hospital on Nov. 27, 1944, with all the obvious features of a fairly well advanced cancer of the upper third of the oesophagus. Examination revealed the usual emaciated patient who was able to locate the site of obstruction quite accurately with one finger at the level of the angle of the sternum. At the time of the first examination he asked for a drink of water, which he swallowed slowly, with difficulty, but without coughing. Inspection, percussion, and auscultation of the lungs did not reveal anything abnormal. An attempted barium swallow, carried out at once, caused choking and had to be discontinued because the fluid was seen to run from the oesophagus into both main bronchi, spreading out in their pulmonary ramifications not unlike an ordinary lipiodol screening. Direct inspection by an oesophagoscope showed a mass extending round and closing the lumen of the upper third. On looking into the trachea a small ulcer was seen at the beginning of the left main bronchus, suggesting a broncho-oesophageal communication.

Gastrostomy was obviously the only possible line of treatment, and, with this in view, the patient was put on an intravenous glucose-saline drip for three days. The operation was then successfully carried out under local analgesia. Following upon this the patient subsisted for 10 days by gastric-tube feeding, but died suddenly at the end of that time.

At necropsy the tumour of the oesophagus, a moderately differentiated squamous epithelioma, was found to be adherent to the vertebral column and the arch of the aorta, and had a well-marked fistulous opening extending from it through to the left main bronchus. The lumen of the oesophagus up above the fistula was narrowed to a great extent, but could nevertheless quite easily have permitted of the running down of fluids. The lower lobes of both lungs were of a solid firm consistency and had a sticky fibrinous exudate over their posterior surfaces, their appearances being those of a confluent bronchopneumonia.

Comment

There was thus no doubt about the existence of a broncho-oesophageal fistula, but how long this had been present before the patient's investigation in hospital is a matter of conjecture. In view of the size of the fistulous opening, however, it seemed quite reasonable to assume that it had been there for some time, possibly weeks.

The outstanding feature of the case was the fact that the swallowing of fluids which obviously passed down directly into the patient's lungs did not set up any acute reaction. There was no coughing on swallowing, nor was there any regurgitation of copious frothy sputum.

From the clinical point of view an accurate diagnosis could not have been made in this case without ancillary aids of investigation, in view of the complete absence of pulmonary symptoms.

Reviews

A TREATISE ON CATARACT

Cataract and Anomalies of the Lens. Growth, Structure, Composition, Metabolism, Disorders, and Treatment of Crystalline Lens. By John G. Bellows, M.D., Ph.D., (Pp. 624; illustrated. 60s.) London: Henry Kimpton. 1944.

Cataract is one of the major problems of ophthalmology. Though surgery gives gratifying results, it can do little for many patients who suffer from severe decline in vision without reaching the stage where operation is either justifiable or feasible. The problem of cataract is thus not exclusively, and perhaps not largely, a problem in surgery. This fundamental truth is brilliantly illustrated by Dr. J. G. Bellows's balanced and monumental *Cataract and Anomalies of the Lens*, a book in the great tradition. A fascinating historical introduction is followed by four chapters occupying almost a third of the book, and dealing with the development, comparative anatomy, growth, structure, chemical composition, and metabolism of the lens. An immense and scattered literature (there are about a thousand references for this section alone) is here surveyed with admirably critical insight. The rest of the text deals with the clinical aspects, and the even more voluminous clinical literature is systematized with the same mastery of the subject and sureness of touch. The different clinical types of cataract are clearly correlated with the embryological, genetic, experimental, and biochemical knowledge that has accumulated, and it is gratifying to find that something like a coherent picture is beginning to emerge out of what at one time constituted a mass of anatomical names. This systematization and clarification, perhaps more than its encyclopaedic range, is the most characteristic feature of this book.

In a foreword the late Prof. S. Gifford compares the book to the earlier study by Hess. This is high praise, but inadequate in this instance. It would be truer to say that Bellows's study has not merely replaced but has surpassed Hess's monumental treatise.

HYPERTENSION AND HYPERTENSIVE DISEASE

Hypertension and Hypertensive Disease. By William Goldring, M.D., and Herbert Chasis, M.D. (Pp. 253; illustrated. $3.50 or 20s.) New York: The Commonwealth Fund; London: Oxford University Press.

This is a book well worth study. Drs. Goldring and Chasis have approached the subject from the point of view of deranged human physiology; that is their attitude to hypertension, and they trace from this at first reversible state the development of the irreversible changes of hypertensive disease. As the authors point out, they have gone back to preclinical studies to do this, and so have aimed at linking more closely physiology and clinical medicine. It is an excellent example and one which might be more often followed.

The book starts with a survey of the types of hypertension and a discussion of the range and value of blood-pressure readings. Then follows a description of the clinical features of hypertensive disease. This chapter is short and bare, making rather dull reading. The authors doubt the existence of a recognizable pre-hypertensive state, and the value of the cold pressor test. Next comes a description of the haemodynamics of hypertension, very clearly set out. They have used catheterization of the right heart for estimation of the output. They agree with the conclusion that vasoconstriction causes the increase in peripheral resistance responsible for the raised blood pressure. A long and very interesting chapter follows on the role of renal function. They have particularly studied the rate of glomerular filtration and the effective renal blood flow, and the excretory capacity and the reabsorptive capacity of the tubules. They conclude that vasoconstriction of the efferent arteriole of the glomerulus, of non-neurogenic origin, is the first abnormal functional change in the kidney. This brings about increase in glomerular filtration but decrease in tubular excretion. The authors doubt the role of unilateral renal disease as a cause of hypertension. Treatment of the disease is discussed with common sense and scepticism, the cause being as yet unknown. They concede that sympathectomy, if extensive enough, may relieve symptoms sometimes, but it does not get rid of the unknown cause. Finally there are appendices giving full data of all their experimental methods.

This book needs careful study and can be thoroughly recommended. The matter is stiff, and the expression is not always as clear as one might wish. The criticism of other work is full and fair. The authors' own opinions are backed up with good reasons. In view of the great volume of work on the subject, largely based on animal experiment, which has appeared in the last decade, this human study is particularly interesting and provides a valuable approach from a different point of view.

DECLINE IN FERTILITY

Race Suicide? By G. F. McCleary, M.D. (Pp. 126. 6s.) London: George Allen and Unwin.

Dr. McCleary's previous contributions to the literature of demography have been characterized by lucidity and fairness; in this book he maintains the high standard he has set himself, with one possible exception to which we shall refer.

In the first chapter he presents the ideals of happiness for its own sake and of duty to which happiness is a corollary, using two well-chosen quotations from Pater and J. S. Mill as texts. In the second chapter he lucidly describes the decline in fertility and how it is measured. In the next chapters the method (birth control) and some of the social reasons are explained. The sixth chapter describes the decline of fertility in the United States of America. In the seventh chapter, which is largely devoted to a criticism of the, sometimes exaggerated, claims of eugenists, Dr. McCleary, we think, falls a little below his own standard of fairness. For instance, speaking of intelligence tests, he writes: "A child of exceptionally intelligent parents achieves a high score in the tests. It would be without warrant to assume that he was born with exceptional gifts; his success may have been due to a life-long association with persons of exceptional intelligence." We should comment that it would be without warrant to assume that this possibility had not occurred to scientific eugenists. There is, we believe, a considerable literature dealing with the differentiation of environmental and inborn factors, and even some on the study of identical twins brought up under different environments.

Chapter 8 studies attempts to increase fertility by legislation, and the last chapter speaks of the future. Whether the appointment of a Royal Commission and a system of allowances for children will have more effect than the legislation of Augustus remains to be seen. Dr. McCleary makes an important point when he shows that in Sweden, a country which has not been at war for more than a hundred years, and has suffered less from others' wars than most neutrals, the decline of fertility has been almost maximal. So a distaste for providing cannon fodder has not been of primary importance as a motive of voluntary sterility. Dr. McCleary says we must have faith in the future of the human spirit. Perhaps the younger generation will.

HEALTH PROBLEMS IN CHINA

China's Health Problems. By Szeming Sze, General Secretary, Chinese Medical Association; editor, *Chinese Medical Journal*. Third edition. (Pp. 76. $1.00.) Washington: Chinese Medical Association, P.O. Box 6096.

The interest aroused in the publication of *China's Health Problems* has encouraged Dr. Szeming Sze to bring out a third (1944) edition. For this the text has been largely rewritten and now includes new sections on the antituberculosis, antivenereal, and antileprosy movements, also on birth control and on nutrition. In view of her unpreparedness for Japanese aggression and her internal political troubles, China's defiance of defeat is truly amazing. War has, however, had the outstanding benefit of emphasizing the magnitude of her health problems and the need for remedial action. China has morbidity and mortality rates which are more than double those of any European country. Of the population 84% live in rural areas and are too poor to pay for private medical care, so that the only solution of this difficulty lies in State medicine, but this in turn must await the provision of an adequate medical profession. If the generally accepted standard of one doctor for 1,500 people is followed China should have some 266,000 doctors. Actually there are only 12,000. Dr. Sze devotes Part II of his book to the status and organization of the National

Health Administration, which controls a number of subsidiary departments—public health, experimental medicine, nursing, maternal and child welfare, and others. Increasingly difficult economic conditions limit much of this work to paper schemes, and we must await the arrival of peace before they can be developed to any practical extent.

One of the Chinese Government's chief responsibilities will lie in the establishment of a higher standard of medical education. At present the number of poorly qualified doctors passing through medical schools of low degree is greater than those from the larger colleges. It is most unfortunate that the Peking Union Medical College, which set the standard for all China and on which the Rockefeller Foundation spent well over £10,000,000, should have been seized and closed by the Japanese. The most active medical body in China is the Chinese Medical Association, which represents the cream of the profession. It has branches in all the main cities and publishes a journal.

This informative report collates the chief problems and puts them in their proper perspective. It is the first of a series of publications relating to the national reconstruction of China.

Notes on Books

A Synopsis of Medicine, by Sir HENRY TIDY, first appeared nearly 25 years ago and soon gained wide popularity. By 1941 it had passed through seven editions and four reprintings, and several thousand copies of another reprint were destroyed by enemy action. Now comes an eighth edition (John Wright and Sons; 30s.). Numerous changes have been made, and the inclusion of new articles and the rewriting of others account for an addition of 40 pages to the text. The greatest advance since the publication of the seventh edition at the beginning of 1939 has been in the region of treatment. "Sulphonamides, then just rising above the horizon, have proved their power over many diseases and saved countless thousands of lives. Some other great advances in therapeutics of recent years have become almost stabilized." The author refers also in his preface to penicillin, "the astonishing substance which will fill many of the gaps still left vacant in the treatment of infections . . . Knowledge of its action is still advancing rapidly, and it has been considered wiser to omit such incomplete and ephemeral references as would alone have been possible at the time of revision."

No. 22 of the *Proceedings of the University of Otago Medical School*, for the year 1945, is edited by Prof. J. B. DAWSON. It comprises twelve reprints of articles on miscellaneous subjects, most of which appeared originally in the *New Zealand Medical Journal*.

T. J. SMITH and NEPHEW Ltd., of Neptune Street, Hull, have produced a new edition of their illustrated publication *Cellona Technique*, a handbook for the functional treatment of fractures, with sections on plaster treatment of tuberculous conditions, soft-tissue injuries, burns, etc. Owing to wartime conditions the number of copies is limited, but the manufacturers will send a copy to any doctor who does not already possess one or whose edition is out of date.

Preparations and Appliances

A SMALL PORTABLE ELECTRO-CONVULSIVE THERAPY APPARATUS

Dr. A. SPENCER PATERSON writes:

The basic requirements of an apparatus for electro-convulsive therapy are not elaborate, and it is because of the additional requirement of maximum possible safety that the machines generally used have been of a somewhat cumbersome nature. Essentially, the function which the apparatus has to perform is to switch on and off a voltage of the order of 100 v. to the electrodes on the patient, with a time interval of 1/2 to 1 second. Alternating current of the ordinary mains frequency serves in an entirely satisfactory manner, and the problem of supply of suitable current is therefore most conveniently met from this source.

To provide the necessary time control, various devices have been used. The chief of these have been motor-driven time switches and condenser or valve circuits operating relays. All such arrangements can, with sufficient care, be made reliable, and they have met the needs adequately. They are, however, either heavy or unduly complex for the simple purpose of switching the current to the patient, and a simplification has been introduced in the present apparatus in the use of an automatic telephone dial for the timing mechanism. This, with suitable modification of its contacts, can be made to switch the current on and off with a time interval exactly equal to the number "dialled" in tenths of a second, and therefore forms a very convenient and simply operated device for the purpose in question.

Selection of the required voltage for the treatment is made by a number of tappings on the secondary of a transformer, connected to the poles of a rotary switch: these tappings are spaced by 10 volts and cover the range 70 to 150 volts, so that any appropriate figure can be chosen to the accuracy that is required in such treatment. This arrangement economizes greatly in weight and bulk compared with the method of voltage control by a high-power resistance in the primary circuit, commonly used.

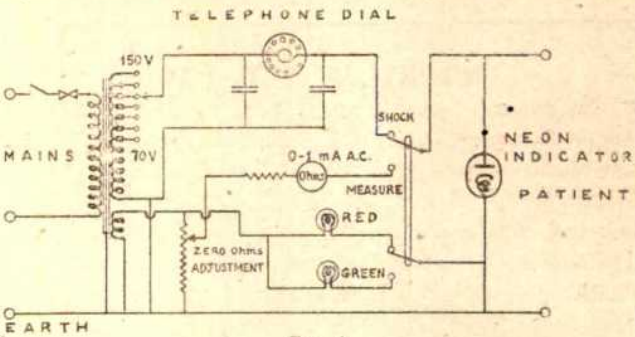

FIG. 1

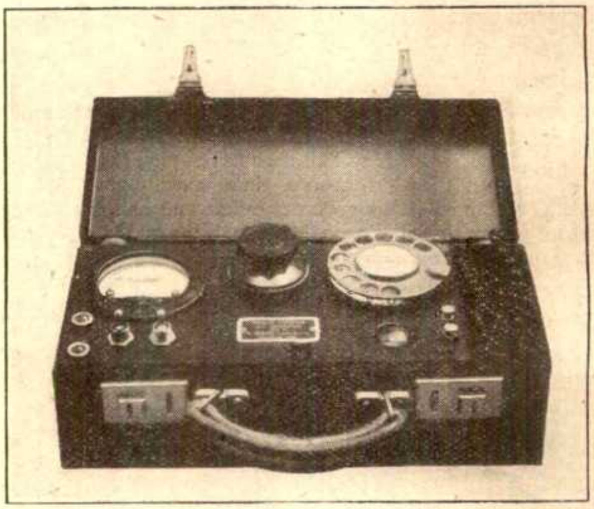

FIG. 2

Measurement of the patient's resistance before giving the convulsion is carried out by connecting a low voltage, of the order of 1 volt, to the electrodes, and observing the current passing through an a.c. milliammeter in the circuit. This meter is calibrated directly in ohms to simplify reading: it must be remembered, however, that the value obtained refers only to the low voltage at which the measurement is made, and the resistance falls very considerably as the voltage is increased. A change-over switch sets the instrument in the "test" or "shock" condition, and indicator lights are fitted to show at a glance which condition is in operation. In addition, a neon lamp is incorporated which glows only for the time the high voltage is switched on: this allows one to test the apparatus by turning the dial before the connexion to the patient is made, and serves as a check that the circuit is "alive."

The circuit diagram is shown in Fig. 1, and a photograph of the finished instrument in Fig. 2. It is made in the most convenient form for carrying, being of minimal size and weight. It is 12 × 5½ × 4 in., the size of a small attaché case, and weighs, including two flexes, 11 lb. It is finished in an inconspicuous manner to this same end. The usual protection by means of fuses as well as an earthed lead in the mains cable are included to give maximum safety to the operator and the patient.

It has been used on a number of patients in various hospitals, and meets the needs of a light portable E.C.T. unit satisfactorily.

I am very much indebted to Dr. Frank T. Farmer, late of the Middlesex Hospital and now physicist to the Royal Victoria Infirmary, Newcastle-upon-Tyne, for his valuable help in the designing of this instrument. It may be obtained from Mr. B. Malme, 423, Hertford Road, Enfield, Middlesex, whose ingenuity has also been of great service.

BRITISH MEDICAL JOURNAL
LONDON
SATURDAY MAY 12 1945

VICTORY IN THE WEST

It was officially announced on Tuesday, May 8, that the war in Europe is over. The prodigious events of the last few weeks, culminating in the fall of great armies and cities, foreshadowed the total surrender of Germany. Expectation had been keyed up long in advance of the armistice. Thankfulness and relief are the uppermost feeling in all minds; but, while it is right to rejoice at the great deliverance in the West, no thoughtful person forgets that victory is not yet in the East, and that British and American ships and planes and men are in peril until Japan capitulates. We remember too the plight of the stricken people of Europe now freed from the Nazi yoke, but still to be brought back to a semblance of normal life. The effect of starvation and under-nourishment and the danger of epidemic conflagration in a disrupted Central Europe are matters which are foremost in the thoughts of doctors. In the peace that will develop, medicine, having played so large a part in war, will, we believe, play an even greater part in solving the problems of the future.

PHARMACOPOEIAS AND THE PHYSICIAN

Dr. F. H. K. Green has given a good account[1] of the Therapeutic Trials Committee of the Medical Research Council, which organizes clinical trials on behalf of manufacturers of drugs, provided certain conditions are satisfied in regard to disclosure of composition and publication of results. Since the scheme was started in 1931 more than 40 new products have been accepted for clinical trial. The Council on Pharmacy and Chemistry of the American Medical Association[2] does not initiate investigations, but it reviews evidence submitted to it by manufacturers. Here again there is a set of rules on composition, nomenclature, advertisement, and therapeutic claims, and articles which are accepted are awarded the council's seal of approval. It is estimated that the A.M.A. council considers from 250 to 400 articles every year. Its book *New and Non-official Remedies* describes 1,300 agents, and the *Journal of the American Medical Association* publishes accounts of individual decisions as well as the council's reviews of new developments in therapeutics. The two bodies are therefore engaged in rather different types of activity—the British committee in clinical research, and the American in the provision of information and ethical nomenclature. The Socialist Medical Association[3] has suggested the creation of a Therapeutic Substances Committee which would combine both these and other types of activity. It not only would control all therapeutic substances and appliances and advertisements of them, but would examine and report publicly on all substances offered or advertised for the treatment of disease or the protection of health. It would also have the duty to prepare and submit to every doctor reports on new remedies, and to recommend their inclusion in or exclusion from the *National Formulary*. A glance at the booklet *War-Time Information for Pharmacists*,[4] and in particular the long list of associations connected with the provision of therapeutic substances, suggests that these tasks would be far beyond the powers of any single committee.

We may doubt whether the present drive to rationalize all our social mechanisms is entirely healthy. Nevertheless, it does appear that arrangements for the codification of therapeutic substances in this country are unduly complicated. The *British Pharmacopoeia*, which is prepared by the Pharmacopoeia Commission appointed by the General Medical Council, is designed to provide standards for those drugs which are in general use throughout the Empire. As these are legal standards, the Commission must err on the side of caution in admitting articles to the *Pharmacopoeia*. During the war, however, the Pharmacopoeia Commission has appointed a committee to choose approved names for new remedies which are under trial and which seem likely to be admitted to the *B.P.* in the future. The *British Pharmaceutical Codex* is prepared by the Codex Committee of the Pharmaceutical Society. It is designed as a book of reference for pharmacists and medical practitioners, and gives standards for many articles not included in the *B.P.*, either because they have fallen out of general use or because they are of recent introduction and have not yet had general acceptance. The *Extra Pharmacopoeia* (Martindale), which is now published by direction of the Council of the Pharmaceutical Society, is particularly concerned with recent developments in pharmacology and therapeutics, and it has made itself an indispensable source of information about new, foreign, and proprietary drugs. Unfortunately in the process it has tended to outgrow its original make-up in two pocket volumes, and a fairly drastic revision of its form and contents will soon become unavoidable. The *Extra Pharmacopoeia* aims at being absolutely comprehensive and inclusive, and therefore differs in purpose from both the *British Pharmacopoeia* and *New and Non-official Remedies*, which aim at being exclusive.

This brief review suggests that the time has come when there should be some more formal definition and integration of the functions of the *B.P.*, the *Codex*, and the *Extra Pharmacopoeia*. An official veterinary pharmacopoeia might also be created. The most vital question is the control of the introduction and nomenclature of new drugs. Many people do not like the word "control," but a seal of acceptance is useless unless backed by control of advertisement as well as by general good will. Direct Government control of advertisements of drugs, as suggested by the Socialist Medical Association, would be violently opposed on political and economic grounds, and it would be difficult to enforce. It is not always easy to say whether a substance is a drug, a food, or a cosmetic. In fact, the same substance may be used for all three purposes. Control by the Pharmacopoeia Commission would be more gracefully accepted, particularly if it took the form of an extension of the policy of approved names. Such approved names could almost certainly be regarded as "the accepted scientific name" for the purposes of the Pharmacy and Medicines Act, 1941, which means that the approved name ought by law to be printed on the label of any container in which the drug is retailed. In addition, the editors of reputable medical journals would probably be willing to include the rule of using approved names in their notice to contributors and advertisers. This policy of approving names will undoubtedly increase the work of the Pharmacopoeia Commission, and it is perhaps appropriate here to record the debt of the profession to it and the Pharmaceutical Society, and to the many men who have served on their committees and subcommittees with so little reward or recognition.

[4] Compiled by the Pharmaceutical Journal, London, 1942.

Clinical trial of remedies is a tremendous task. The evaluation of a single remedy for hypertension or for cancer may take years and must consume a corresponding amount of the time of valuable investigators. The arrangements suggested by the Socialist Medical Association might well result in political pressure on the research worker, and politicians are not necessarily good judges of therapeutics, as some of them have shown in recent years by misguided enthusiasm for alleged remedies for incurable conditions. The complaint against the Therapeutic Trials Committee is that it moves too slowly, and certainly during the war the tendency has been to short-circuit it and use *ad hoc* organizations, as in the trials of penicillin and patulin. In any event a manufacturer would wish to have a strong case before approaching a body like the Therapeutic Trials Committee, and to begin with he may prefer to make contact with an individual investigator or group of investigators who are interested in the particular field and capable of making tests. Clinical trials may be better carried out in local authority hospitals than in teaching hospitals or key hospitals. The researches on the treatment of meningitis in L.C.C. hospitals[5] and on pneumonia in Glasgow[6] are models of their kind. The Local Health Services Councils may one day provide a mechanism for the promotion of large-scale trials where these are necessary. The days when testimonial evidence could be offered are over, and conclusions on therapeutics must be statistically sound. Trials of this kind will often be enough to show whether a new remedy is acceptable, and it may only be necessary to invoke the more elaborate mechanism of the Therapeutic Trials Committee in special cases. Reputable manufacturers are just as anxious to know the truth as clinical investigators, for they do not wish to embark on heavy expenditure in manufacturing a drug which is not efficacious. There is no reason why manufacturers should not bear the cost of clinical investigations, provided the financial arrangements are approved by the university or hospital authority whose laboratories or wards are being used. But in the final court of appeal—the Medical Research Council Therapeutic Trials Committee—the rule must continue to be enforced that there must be no financial arrangement or contact of any kind between manufacturer and clinical scientist, to avoid the slightest suspicion of bias.

THE REPRESENTATIVE MEETING

Although the contents of the document circulated by the Association to its members have leaked out on to the pages of the lay press, we are still under an obligation to the Minister of Health not to disclose publicly the administrative proposals which were discussed at last week's Representative Meeting. It should be made clear that the secrecy shrouding these discussions is regretted by the Association, which has to adopt the expensive measure of circulating a confidential report of the meeting to every member of the profession. This will be sent out in the near future. From the point of view of the Minister it would apparently be improper for him to allow publication of new proposals until they have been put before the House of Commons. It is necessary to appreciate this point of view of procedure and to respect the Minister's wishes. What we do deplore is the hectoring attitude of some of the self-appointed critics of the medical profession, a few of them, indeed, being inside the ranks of the profession. Their curious view of the method of negotiation seems to be that those who represent the profession should accept the Government's first words without demur. This lop-sided view of democracy is one which hitherto has been more popular on the Continent than in this country. Fortunately the Minister of Health has stuck to the Government's view that the White Paper was published as a basis for discussion with the various interests concerned, and that legislation would not be introduced until full discussions had been held. That there has been give-and-take in the discussions between the Negotiating Committee and the Ministry is wholesome evidence that democracy still works. The voices that have shrieked "No concessions to the doctors" are unfortunate evidence that democracy is not so secure as many of us would wish to think.

There is no doubt that at the meeting last week the Representatives appreciated the hard work the Negotiating Committee had put in, and, by their voting on some outstanding issues, believed the results of the negotiations to be such as to provide a sufficient framework for the proposed National Health Service. It would, however, be erroneous to pretend that the meeting felt happy about the position with which the profession is faced—a discomfort that was reflected in the recurrent appeal, "We must be realists." On one issue that has perplexed many—the 100% issue—the meeting hardly needed to be reminded that 60% of those who answered the Questionary were in favour of including the whole population in a comprehensive health service. The many debates on this subject during the past three years have made it more and more evident that it is illogical to try to exclude one-tenth of the population of this country from a National Service. It would certainly be very difficult to persuade the lay public that exclusion of 10% was in some way bound up with professional freedom. But the fact that many medical men have fought against the 100% issue is in itself a sign of the general distrust a strongly individualistic profession has for administration by central and local government. Those who finally build the new service will have to take this distrust into full account, and will be successful in removing it only in so far as they ensure that the medical profession has a predominant voice in the running of a highly technical service, the contents of which are a closed book to the majority of laymen. The layman is, indeed, probably more ignorant of medical science than of any other science, pure or applied.

---

[5] Banks, H. S., *Lancet*, 1938, 2, 7.
[6] Anderson, T., *et al.*, ibid., 1939, 2, 776.

If, in the future political development of this country, central control and direction increase to the point at which the individual controlled begins to lose a sense of full responsibility for what he does, then the quality of service will deteriorate, and the servant will devote much of his energies to making quite sure he does not do one iota more than what he considers he is paid for. Doctors as a body are in a weak position in comparison with other sections of the community, for the humanitarian nature of their work forbids their resorting to the political device of the strike. We can only hope that the country will not abuse this position by exploiting the fact that no medical man would ever refuse to go to the assistance of a sick person. The new service must be so evolved as to give the doctor the fullest scope for practising his art, which is still largely an individual art applied to individual men and women.

PRESIDENCY OF THE B.M.A.

During the past two years two Presidents of the British Medical Association have died while in office—Sir Beckwith Whitehouse and Viscount Dawson of Penn. The Council at its last meeting on May 2 was faced with the position hat there was no Immediate Past President to fill the vacancy caused by Lord Dawson's death, and under the by-laws it fell to the Council to provide for the discharge of the duties of the office until the next Annual Representative Meeting. The Council decided to appoint Mr. H. S. Souttar as President until the next A.R.M. in July, and to recommend to the Representative Body the election of Mr. Souttar as President in respect of 1945–6. It is a great advantage to the Association to have now as its titular head man who has served it in a succession of high posts, culminating in the Chairmanship of Council during the first four years of this war; he has also been Chairman of the Central Medical War Committee and of the Medical lanning Commission, and was Chairman of the Representative Body in 1934–7. Mr. Souttar is in active practice s a surgeon to the London Hospital, and recently held office as Vice-President of the Royal College of Surgeons of England. Apart from his eminence in the profession and his many public services our new President is known o a large proportion of the members at home and abroad or the kindness and grace of manner which are part of his nature.

ARCHIVES OF DISEASE IN CHILDHOOD

With its 101st number the *Archives* enters upon a new hase, for it now incorporates the *British Journal of hildren's Diseases*. It is therefore a suitable moment o record the brief history of these two journals and to ake a glimpse at the future. The *British Journal of hildren's Diseases* made its first appearance in 1904 under he editorship of the late Dr. George Carpenter, who, in n editorial note, observed that in the British Isles there as then no periodical which dealt with disease in childood, although America, France, Germany, and Italy were aking headway in this special field of medical journalism. In 1900 the Society for the Study of Disease in Children had been founded, and undoubtedly its growing strength astened the birth of a special journal. Carpenter was much helped in his enterprise by the late Mr. R. E. Adlard, of the printing firm of Adlard and Son, Ltd. Dr. Carpenter had saved the life of one of the children of Mr. Adlard, who showed his thankfulness by launching and financing the *British Journal of Children's Diseases*, now no longer published as a separate periodical.

The *Archives of Disease in Childhood* first appeared in 1926, largely through the energies of the late Dr. Hugh Thursfield and the late Sir Dawson Williams, then Editor of the *British Medical Journal*, who retained a life-long interest in diseases of children. The new journal was welcomed in our columns in these terms: "Nearly a year ago some of the medical men whose work lies chiefly among children, and who for a considerable time had felt that English work in this branch of medicine was inadequately presented by existing publications, met together, and after discussion determined to sound their colleagues on the advisability of establishing a new journal." The high literary and scientific standard set by the *Archives* has been worthily maintained by its Editors, and the current issue, the first run of the second hundred, sees it strengthened by its absorption of another journal and by the formal recognition of the strong link that exists between the *Archives* and the British Paediatric Association. The appointing of editors and editorial committee and board is now a joint function of the B.M.A. and the B.P.A. The British Paediatric Association has, in recent times, shown its active concern with the preventive aspects of child health, and no doubt this will be reflected in the editorial policy of the *Archives*, which should therefore have a wider appeal in the future, especially to those practitioners whose work among children is associated with that of local health and education authorities.

Much of the preventive medicine of childhood must rest upon the scientific study of disease. The recognition of the disease rickets, for example, and the discovery of its cause have made it possible to plan preventive measures in a scientific way; and so with scurvy. Protective inoculation against such infections as diphtheria, the diagnosis of foot faults and faults of posture, the study of the abnormal behaviour of the "problem child"—all these are witness to the fact that the approach to health has often to be made by a study of the abnormal. The standards of the normal, of "positive health," are but little known, so the title of the *Archives*, if it does not reflect the new optimism, at least reflects what is and not what might be.

THE ASSOCIATION OF SURGEONS

Early in 1914, in a letter to Sir Rickman Godlee, Sir Berkeley Moynihan suggested the setting up of an Association of Surgeons of Great Britain and Ireland. The war of 1914–18 postponed a decision on this, and it was not until January, 1920, that the Association was in fact founded, Sir John Bland-Sutton being elected its first president. The number of Fellows was limited to 250, and the objects of the Association were declared to be the advancement of the science and art of surgery and the promotion of intercourse and friendship among the surgeons of the United Kingdom. The new association took over the *British Journal of Surgery*, which had up till then been managed by a committee of surgeons, but any Fellow reading a paper at a meeting of the Association was to be at liberty to publish it where he wished. Last week the Association met under its new president, Surgeon Rear-Admiral Gordon-Taylor, and completed a day's programme by assembling at a dinner to which many distinguished guests had been invited. There were only two speeches. Sir Alfred Webb-Johnson, in proposing a toast to the President, paid a graceful tribute to him as a surgeon-anatomist and a man of wide culture. In reply, Admiral Gordon-Taylor gave the audience an example of his mastery of oratory, when, by the device of fantasy, he conjured up some of the recent great figures in the history of surgery. In these rather bleak days the large number who attended the dinner were evidently delighted at the opportunity of once more promoting the fellowship of the Association of Surgeons of Great Britain and Ireland.

HEART INJURY

Damage to the heart is so often fatal that the account by Hugh Barber[1] of cases in which the patient has survived is of much interest. They had suffered non-penetrating injuries. The sort of accident which leads to these are blows on the thorax, in particular from the steering-wheel in motoring collisions, crushes, and occasionally falls. External injury may be slight; the thoracic cage is very elastic and the heart may be damaged although no bones are broken. Rupture of the heart may cause death at once, but contusion of the myocardium is compatible with life and not uncommon if it is looked for. The damaged area may rupture later. Routine examination of the heart by the electrocardiograph may give useful evidence. Abnormal curves may be found in about a quarter of the cases, and Barber shows the value of taking records as soon as possible after the accident; as many changes are transient, repeated tracings must be taken. Changes in the T waves are the most frequent findings. Pericardial friction is a useful diagnostic sign, but it does not last long. The early diagnosis of haemopericardium is important for the patient, because tamponade may develop if the effusion of blood is at all large. This is an urgent indication for relief by aspiration; the signs are rising venous pressure and pulse, and falling blood pressure and pulse pressure. Physical signs of myocardial contusion are not conspicuous —possibly nothing more definite than weakness of the sounds. After a latent period signs of failure may come on, with frothy expectoration, dyspnoea, falling blood pressure, and rising pulse rate.

Most cases of myocardial contusion probably clear up completely. Sometimes angina of effort may persist, and sometimes a sort of effort syndrome. Occasionally an aneurysm of the ventricle may be found later. Diagnosis becomes more complicated when there has been antecedent myocardial disease. There appears to be good evidence that coronary thrombosis may be precipitated by trauma when the arteries are already diseased. There is no doubt that auricular fibrillation may arise from injury, as may paroxysmal tachycardia; also sinus bradycardia and occasionally heart-block. Rupture of the aortic and mitral valves has been known for years as a result of severe physical effort: direct violence may rupture them. These findings have a good deal of medico-legal importance in assessing damages when disability results. Fortunately it appears that contusion of the myocardium is unlikely to have a permanent effect on a healthy heart. It is evident that special care should be paid to the examination of the heart after precordial injury, and an electrocardiogram should be taken as soon as possible. The differentiation of antecedent disease and the effects of trauma may give rise to knotty problems in a court of law.

THE MENTAL HOSPITAL

In March, 1943, there was an outbreak of amoebic dysentery at one of the New York State mental hospitals, and the scandal which resulted led Governor Dewey to appoint a Commission to inquire into the administration of these hospitals. General physicians and hospital administrators were represented on the Commission, but psychiatrists only among its advisers. The report of the Commission[1] has therefore a somewhat fresh point of view.

The Commission was unpleasantly surprised to discover the extent to which the State mental hospitals had been allowed to become custodial institutions rather than hospitals in the true sense of the word. The hospitals were understaffed. The State Department had set itself a goal of one physician to 150 patients, but this had never been achieved. Too much of the time of the available physicians was taken up with the care and treatment of the physical ills of the patients. This could be better handled by a staff of "internes," assisted by visiting physicians. Arrangements for active treatment were chaotic. In some hospitals they were available, in others not. A patient's chance of recovery depended on the accident of which hospital he came to. Dementia praecox accounted for a quarter of all admissions and led to an average stay in hospital of 19.3 years. In a second report[2] the Commission has recommended that insulin treatment should be made available to all such patients in the State hospitals. Insufficient interest was also shown in putting the maximum number of patients on parole and in arranging where possible for family care. The State allows $8 a week for every patient in family care, and the Commission considered that, when the cost of maintenance and new construction was allowed for, this was cheaper than institutional care. In the life of the hospital physician an undue part was played by administrative duties. The superintendent did a great deal of the work which should be the province of a business manager, an official who should take the place of the existing steward. In turn the clinical director found himself tied to a desk job. The best positions in the service were reserved for psychiatrists who became administrators; it should be possible to make a career also along clinical lines. There was too wide a gulf between the salary of the superintendent ($8,500–$10,500 per annum) and that of the first assistant, clinical director, and steward ($5,200–$6,450 per annum). Clinical and research interests should be fostered in other ways. To combat "ingrowing tendencies," each institution should have a travel study fund to enable members of the medical staff to attend important professional meetings and to visit centres where noteworthy medical work is being done. Other criticisms of existing arrangements deal with dietary, occupational therapy accounting, business management, etc. Overcrowding of the mental hospitals is serious. The Commission considered that the medical care of the tuberculous was "nothing less than shocking," and it recommends establishing one or more special hospitals located near those maintained by the State Department of Health.

This report has itself met with strong criticisms,[3] into the merits of which we need not enter. It is, however full of lessons for the British as well as the American psychiatrist and hospital administrator. The New York State hospitals include some of the best in the U.S.A., and as a group they are probably more advanced rather than more backward than any corresponding service in this country.

Dr. Charles Hill, Secretary of the B.M.A., is standing as an Independent candidate for the University of Cambridge at the coming election. One of the present representatives of the University, Prof. A. V. Hill, has intimated his intention of not standing again.

RHEUMATISM: POSTGRADUATE INSTRUCTION

BY

Sir ADOLPHE ABRAHAMS, O.B.E., M.D., F.R.C.P.

Physician to Westminster Hospital; Consulting Physician to L.C.C. Hospitals

Rheumatism may be conveniently defined as a painful disorder of the locomotor system the aetiology of which is obscure. Anatomically this conception will embrace the joints, the fibrous tissues, and the neuromuscular system throughout the body. Symptomatically, it is no exaggeration to say that it may be applied to the occurrence of pain in every inch of the body—quite literally from the scalp to the sole of the foot.

Very early in my professional life I was impressed by the observation "Beware of rheumatism" by an experienced general physician in the course of his lecture on "Errors of Diagnosis." "Which of us," said he, "has not let out rheumatism with a scalpel?" Osteomyelitis is not the only serious error in differential diagnosis. We recall tuberculous arthritis and scurvy. The tabetic with lightning pains will present himself with the complaint of "rheumatism." Vague so-called rheumatic pains in the limbs will be recognized as the manifestation of trichiniasis by an astute observer who has noted oedema of the eyelids. As a contrast, there is the misaken diagnosis of progressive muscular atrophy or a dystrophy when rheumatoid arthritis and trophic muscular changes were he correct explanation.

Cardiologists have associated the symptomatology of disease of the shoulder girdle or subacromial bursa with angina pectoris. The subjects of coronary arteriosclerosis have sometimes been egarded as suffering from these lesions for considerable periods. Pain more or less constant in the shoulder region—most commonly the left but often the right—has developed within an nterval of three or four months after myocardial infarction nd lasted for several years. The shoulder pain has even preceded coronary thrombosis for as long as a year. It is supposed that reflex hypertonus of the muscles of the shoulder irdle plays some part in the simulation of arthritic disease.

Charcot's joints, Paget's disease of bone, and, most tragic of all, malignant disease of the vertebrae or of the spinal cord are other lesions which have been mistakenly regarded as so-called rheumatism. Within a fortnight I saw three examples of arcinomatous metastases, two diagnosed as "sciatica" and one s "brachial neuritis." All three had been under the care of pecialists at spas—men of experience at least as considerable s my own. I record these cases in no spirit of superiority, but as providing a salutary and humbling lesson. In all probability, how often must I have perpetrated similar mistakes!

And so while the specialist in rheumatism may be regarded y the layman as a man with rule-of-thumb methods of physical therapy—to us who reflect upon the traps and pitfalls, the difficulties of diagnosis, he must be recognized as an exceptionally gifted member of the profession, in his approach to very branch, to every system.

Aetiology

I ventured to begin with the generalization that aetiology is obscure. It is not surprising that every possible pathological element in the causation or reputed causation of recognized diseases and lesions has been presumed as an essential or necessary factor, with the unfortunate corollary that much work as been undertaken in watertight compartments instead of determined campaign to correlate in the avoidance of rash eneralizations.

We know that degenerative processes, the inevitable wear nd tear of structures concerned in locomotion, must in some nstances be responsible to an extent which has led to a fatalistic cceptance of the inevitable, the irrecoverable, and to a conlusion merely to make the best of a bad job. The influence of toxaemia waxes and wanes in popularity. Ruthless eradiation of teeth, of tonsils, of gall-bladders, of appendices, of pelvic viscera, with resulting disappointment, has on the whole ncouraged the complete abandonment of this therapeutic approach even if the diehards, deprived of any evidence of the influence of removable foci, still invoke the existence of hypothetical toxins in the interior of the gut.

Metabolic possibilities have naturally provided a wealth of hypotheses, whether along the lines of digestive insults with the presentation of all sorts of dietetic regimes, or on the principle of vitamin deficiencies.

Very naturally the endocrines have come in for their exaltation in importance; more especially as the relationship of arthritic lesions to menstruation, to pregnancy, and to the menopause is in some instances acceptable. Climatology one recalls only briefly in passing. It is a factor which almost everybody is prepared to accept as of some influence, but as one which with very rare exceptions has received the most trivial scientific exploitation.

Of recent date the psychosomatic side has been emphasized to an extent which makes an overwhelming appeal to the psychologically minded. That the emotional disturbances engendered by environmental burdens—poverty, grief, worry, and the like—have a distinct relationship to the onset and exacerbations of rheumatoid arthritis requires no emphasis in endorsement. But the majority of us pause to consider whether or no we shall accept so literally the explanation advanced of symbolic presentations of fibrositis as, for example, "feeling stiff and sore" over some grievance or frustration; of "unbending pride" through resentment; of "inability to stoop" or "lower oneself" to a certain course of action; of "getting it in the neck," both literally and figuratively; of representing through "sciatica" the desire to kick somebody, or through "brachial neuritis" to indulge in fisticuffs.

Yet something psychological may be advanced at least in partial explanation. The most materially minded will be prepared to accept the possibility of emotion leading to muscular spasm and tension, or inducing vasomotor changes which bring about localized areas of ischaemia or which lower the threshold of sensitiveness to external physical agents.

I have ventured to suggest that progress in therapy has been retarded by the tendency of men able and efficient in their particular spheres, yet unduly obsessed by their restricted applications, to reduce their sphere of usefulness by remaining in their watertight compartments. Each and every one of their methods of approach may well have a bearing more or less significant in individual instances, more or less applicable to the subject as a whole. Enthusiasm counts for much in explanation of the presentation of therapeutic virtues and the equally numerous pessimistic repudiations, when one specialist working with a new material or method reports dramatic successes and another reports complete failure.

The future health policy, the Government announces, is to include the treatment of rheumatic sufferers. To implement this intention it is proposed to establish and staff a number of rheumatism treatment centres. These will demand the provision of medical practitioners with special knowledge in the diagnosis and treatment of the rheumatic diseases, and it is the opinion of the Empire Rheumatism Council that it is desirable in the interests of the public health to institute postgraduate courses to enable a number of medical practitioners to acquire that special knowledge.

I need not refer to the nomenclature of "the rheumatic diseases" as agreed by the Committee on Chronic Rheumatic Diseases of the Royal College of Physicians (1936), but I venture to think that the brief survey I have presented of the scope of what may be legitimately included, and of the difficulties and possible pitfalls in differential diagnosis, sufficiently indicates the importance of instituting a comprehensive course of postgraduate training.

It is at this stage premature to describe the exact steps which must be taken in the selection of suitable trainees and to decide if they shall possess special qualifications that may be regarded as a *sine qua non*, or to do more for the present than anticipate that training grants will be available from public funds or from other available sources to permit of their whole-time attention. The facilities for appropriate instruction available at teaching hospitals, postgraduate schools, rheumatic treatment centres, orthopaedic centres, and the like are also matters which are at present under consideration; and the remuneration of teachers employed must also be a necessary item in the scheme that is proposed.

But it may be permissible to give some indication of the syllabus envisaged and to state that, in order to attract the right type of entrant for this specialty, a preliminary course (three months) on general medicine at the Postgraduate College or similar institution should be undertaken especially with the encouragement to take a higher degree or diploma. A suggested syllabus of the course itself may now be outlined.

A Suggested Syllabus

Aetiology.—Survey of the recent trends in aetiological concepts in acute and chronic rheumatism and arthritis, including toxic, metabolic, climatic, dietetic, and traumatic factors and possibilities.

Pathology.—The classification and pathology of acute and chronic rheumatic diseases (including gout and spondylitis). Morbid anatomy and histology.

Applied Anatomy and Physiology.—(*a*) Surface anatomy: body mechanics and posture. (*b*) The structure and action of muscles and joints. (*c*) The skin and its reactions. (*d*) The blood, the circulation, and respiration as they affect the locomotor system. (*e*) The nervous system with reference to: (1) Segmental and peripheral nerve distribution. (2) Pain: the methods of causation, transmission, reference, and clinical application.

Radiological Investigation.—The normal radiology of bones and joints. The radiology of the rheumatic and pseudo-rheumatic diseases.

Clinical.—(The chief rheumatic diseases will be dealt with during the course in general medicine. Such "rheumatic symptoms" as occur in poliomyelitis, tuberculosis, gonorrhoea, osteomyelitis, leukaemia, etc., may be mentioned.) Standardized history-taking and the recording of symptoms. Orthopaedic aspects: postural and congenital abnormalities; chronic strain. Neurological aspects: neuritis, prolapsed disks, "hysterical joints," the mechanism of pain reference, muscular dystrophies; "sciatica."

Therapy.—Physical medicine: demonstrations of apparatus and methods in use; remedial exercises and physiological rest; the writing of prescriptions. Re-education of muscles and joints: occupational therapy. Reconstructive surgery of joints. Specialized methods of treatment: gold salts; procaine injections; aspiration of joints. Simple plaster work. Vaccines. Manipulation. The prophylaxis and treatment of acute rheumatic fever.

(N.B.—Practical experience of all the above should be acquired when working as a clinical assistant in rheumatic and orthopaedic special departments or hospitals.)

Social Medicine.—Environment; housing; dietetic, psychological, traumatic, industrial, and occupational factors.

Finally it may be pertinent to recall the close co-operation between orthopaedic specialists and "rheumatologists" advocated by the joint committee of the Empire Rheumatism Council and the British Orthopaedic Association, and the agreement of these bodies in their joint memorandum to the Ministry of Health as regards the organization and, where possible, as regards buildings, for the establishment of a decentralized scheme of out-patient and treatment centres depending upon a central hospital department. It would appear desirable for trainees to spend three months in an orthopaedic centre. The replacement of the title "orthopaedic physician" for "rheumatologist" might well be considered.

EMPIRE LEPROSY RELIEF ASSOCIATION

TWENTY-FIRST BIRTHDAY APPEAL

On April 26 at the Mansion House an appeal for £210,000 was launched at the coming-of-age meeting of the British Empire Leprosy Relief Association (B.E.L.R.A.)—that is, £10,000 for each year of its work. The Lord Mayor, who was accompanied by the Lady Mayoress, in opening the proceedings read a message from the King, who is patron of the association. Messages in support of the appeal were also read from the President, Lord Halifax, and from Lord Wavell, Viceroy and Governor-General of India.

Sir **ALFRED BEIT**, M.P., represented the Colonial Office in the absence through indisposition of the Colonial Secretary, Col. Oliver Stanley. He spoke of the long and fruitful collaboration and consultation of B.E.L.R.A. with the Colonial Governments, which would need not only to be sustained but extended in the future. Although the various Governments concerned had not been inactive, it could not be denied that measures for the relief of leprosy are still inadequate, and the Colonial Governments would desire to be associated with the tribute he was paying to the association. The newly passed Colonial Development and Welfare Act would be able to provide some of the required assistance, as in the case of the recent grant to Nigeria, but the Colonial Office hoped they would be able to rely on receiving help from B.E.L.R.A. in the future as in the past. The tours in the Colonies of medical secretaries of the association had been greatly appreciated, and further research work was essential. Last year he had witnessed for himself the leper settlement in Southern Rhodesia, with the remarkable record of 50% of cures as a general average. Equall good work had recently been carried out by Dr. Ernest Mui in the Trinidad Leper Settlement.

Achievements and Aims

Sir **BERNARD BOURDILLON**, chairman of the Executive Committee paid a tribute to the three founders of the association—Sir Fran Carter, recently deceased, Sir Leonard Rogers, and the Rev. Fran Oldrieve, the first secretary. He need not go into the history an twenty-one years' work of B.E.L.R.A. because the visitors had bee supplied with a pamphlet on the subject by Sir Leonard Rogers He paid a tribute to the good work of Toc H volunteers inspire by their founder-padre. He considered the time to be overripe fo a whole-hearted drive to exterminate leprosy in the British Empire It was only through the investigations of the last twenty-one year that the immensity of the task had been realized with the discover that there were probably about two million sufferers from lepros in our Empire—a far larger number than had been previousl suspected. Thirty years ago the only recognized treatment for leper was what amounted to imprisonment for life; this led to conceal ment of cases. Now we knew that far the more common neur cases were seldom infective, and therefore did not need segregatio and that if the disease was taken early enough it was susceptible t treatment. For example, when he was acting as Governor of Ceylo fifteen years ago the 600 known lepers were isolated. Soon afte as the result of a visit from the association's medical expert, th new methods of control were introduced into Ceylon, and a surve increased the known numbers to over 3,500. Only the infectiv cases were isolated, and all received treatment, with the result th from 1941 onwards new cases had declined and a start had bee made towards eliminating the disease from the island. Two and half years ago he had visited, as Governor of Nigeria, two enormo mission leper settlements in Southern Nigeria, whose work ha received 100% co-operation from the whole population. He ha been so convinced that "here is a magnificent work on absolute sound lines which must be extended until we gradually cover t whole country" that he got his Director of Medical Services prepare a scheme for a capital expenditure of £58,000 and an annu expenditure of £40,000 for five years. Col. Stanley at once provide the money from the Colonial Development and Welfare Fund. B this sum would only suffice for the three worst-infected of the Provinces of Nigeria, and one-third of the total lepers. Hence t necessity for the most liberal support of the present appeal B.E.L.R.A., who wanted in addition to extend their methods many other colonies. Twenty-one years ago the association rais only £4,000 by their first appeal, but subsequent efforts had enabl them to spend just over £100,000 on actual work in the field. announced the receipt of a gracious gift from His Majesty. T United African Company had given the splendid sum of o thousand guineas, and Barclay's Bank and John Holt and Co. £5 each.

First-hand Experiences

Dr. E. **MUIR** spoke of his wartime work at the beautiful isla leper settlement of Trinidad. He traced the spread of leprosy the Western Hemisphere after its discovery. Good progress h been made since Trinidad had modified its stringent Leper Segreg tion Act to allow early cases of a mild type to be treated in spec out-patient clinics, in accordance with B.E.L.R.A. principles. India and Africa admission of lepers to the modern type of agric tural colonies was now regarded as a privilege; no compulsion w required. Conditions were much more difficult under the compulso segregation system in Trinidad, but patient work had improved t atmosphere of that settlement. The introduction of improv methods of treatment had done more than anything else to remo the sting of compulsion. Last August an American firm had su plied him with a new synthetic sulphonamide, which had been ported to be effective in tuberculosis, and which had been favoura reported on in the U.S.A. Carvile Leper Settlement. This had giv encouraging results in the hands of Muir at Trinidad and h increased the cheerfulness of the patients. With regard to t future he pointed out that B.E.L.R.A., in co-operation with vario missionary societies, had been to a large extent responsible f pioneer work, and the demonstration of methods along which lepr could be dealt with effectively. The arrangement for the Niger

Government to take over and extend much of the work there would free B.E.L.R.A. to concentrate on other parts of West and East Africa, the Sudan, and other colonies. Work was urgently needed to test new remedies, for the discovery of a real cure for advanced and highly infective cases did more than anything else to hasten the elimination of leprosy. The best birthday present to B.E.L.R.A. was the provision of ample funds to enable the open sore of leprosy to be healed throughout our Empire.

Mrs. **GRAINGER**, who has recently returned from many years of work in Nigeria, latterly spent at a missionary leper settlement with 15,000 patients under treatment, spoke eloquently on her experience. She emphasized the importance of caring for the children of the patients to save them from infection, and the joy of handing back their healthy children to mothers who were being discharged cured from the settlement. The proceedings terminated with a vote of thanks to the Lord Mayor and the Lady Mayoress moved by Sir **LEONARD ROGERS**.

MEDICAL SERVICES IN TRINIDAD

SEVERE CRITICISMS BY GOVERNOR'S COMMITTEE

A committee to review the medical and health policy of the colony of Trinidad and Tobago was appointed by the Acting Governor in August last. By arrangement with the Secretary of State and the medical authorities in Scotland, Col. Sir Alexander Russell was appointed chairman. Of the four other members of the committee two belonged to the medical and two to the legal profession. Evidence was given by many public bodies and associations, including the Northern Division of the Trinidad and Tobago Branch of the B.M.A., and by the oilfields companies and sugar estates, and the heads of Government Departments submitted memoranda. The report of the committee, which has been laid before the Legislative Council, contains as many as 160 recommendations.

"Grossly Deficient"

The committee finds the medical staff of the Health Department, as a whole, to be grossly deficient, though the deficiency s relatively less on the medical than on the public health side.

> "When due allowance is made for the war, and the admitted hortage of medical men, there appears to have been no real effort, even before the war, to build up a staff sufficient to deal with both the usual and the more specialized aspects of curative medicine."

Apart from this, the committee found evidence of a certain "lack of keenness" and lack of *esprit de corps* and spirit of service among a considerable proportion of the medical staff of the Department. This deplorable situation, it believes, is largely due to the absence of a proper system of staff organization, and, as regards the hospitals, to the lack of a grade of house-physicians and house-surgeons. Another cause is the unatisfactory method of granting study leave and of selecting officers for promotion. The specialist service is also declared to e very inadequate, while the district medical service is "depressing in the extreme," in some areas so deficient as to be virtually on-existent. There is no regular system of appointment of district medical officers, full-time, part-time, and contract officers eing appointed in a haphazard manner without due regard to he size of the area or the needs of the population.

> "We have heard numerous complaints of inaccessibility, hardship, exorbitant fees, callousness, and even sheer neglect in connexion ith the district medical service; and it seems to us that these are ound to persist until the whole service is thoroughly reorganized nd established on a satisfactory basis so as to ensure that even a poor labourer in a remote country district, in case of need, can btain speedy and effective treatment."

On the public health side of the Health Department the usual ctivities are to be found, yet in the absence of a stated policy the public sees in these activities only spasmodic and uncorreted effort. The committee adds that it

> did not receive that assistance we anticipated from witnesses as gards the formulation of a medical and public health policy. On e contrary, most of them, individuals as well as associations and cieties, were principally concerned with, and devoted most of their written and oral evidence to, pointing out defects of the present stem. In fact, it is true to say that we rarely received any conuctive suggestions."

Proposals for Reorganization

The committee suggests as a long-term policy the reorganizaon of the medical service in accordance with certain proposals it lays down. Among its proposals is the appointment of a medical officer of health for each county, to have control of health staffs and to be responsible for all health activities in the area. One innovation suggested on the medical side is a united specialists' service for the whole of the British West Indies. It is considered that the present method of classifying medical officers in the colonial hospitals into Grades A, B, and C should be extended to all officers in the medical services, and a further grade D created to include house-physicians and house-surgeons. An officer should be up-graded to A only if he possesses an advanced degree, and to B only if he has taken a period of study leave and has gained an additional qualification from a British university.

On the question of private practice the committee says:

> "We do not think it is the duty of the Government to provide medical service for the whole population; that is not a generally recognized Government function in any part of the world. But we think the policy of the Government should be to encourage the settlement of private general practitioners in rural and semi-rural areas, and one of the most certain methods of achieving this aim is to forbid private practice to all Government medical officers."

The only exceptions to this should be in certain scantily populated areas where it is unlikely that any private doctor would care to settle without a monetary inducement of some kind. It is affirmed unhesitatingly that the employment of part-time district medical officers is unsatisfactory and should cease at the earliest possible date. County and district medical officers should be fully occupied and have no time for private practice.

Other proposals are for a central advisory committee, the Director of Medical Services to be chairman, one member to be nominated from the Legislative Council, one to be nominated by the Northern and another by the Southern Division of the B.M.A. Branch, and one each to represent the Port-of-Spain and the San Fernando municipal councils. The committee recommends that all the sugar and oil companies should be required to provide a satisfactory medical service for their employees, and that the shipping and industrial interests of Port-of-Spain should provide a health centre, ambulance service, and full-time medical officer for the treatment of emergency cases arising among their workers.

Much public criticism has centred around the colonial hospital at Port-of-Spain.

> "We have evidence to show that a number of the complaints are justified, some of the medical officers being equally responsible with the nurses in respect of delayed and careless treatment, lack of kindliness, and even neglect. . . . We have had evidence, which we accept, of a certain number of deplorable incidents which are bound to reflect on a hospital's good name."

On the other hand, many complaints are second-hand or third-hand stories. The committee believes that the general proposals made with regard to staffing will go far to improve conditions. The appointment of medical staff committees and the closer contacts which it is recommended that the director and deputy director should have with the staffs may do much to dispel suspicion and resentment. All the hospitals which the committee saw require complete reconstruction, and a very unfavourable opinion was formed of the district hospitals.

Many other recommendations are made concerning specific services, and appointments, promotion, and leave of medical officers. Finally, in place of the present Medical Board, it is proposed that a new controlling body, the Medical Council of Trinidad and Tobago, should be set up to take over the registration and discipline of medical practitioners. It should consist of twelve members, all belonging to the medical profession, nine of them elected by the registered medical practitioners of the colony, and the other three nominated by the Government.

Government's Reply

In a short covering memorandum the Government states that it has no desire to minimize the severity of the strictures on the medical services of the Colony, except in so far as they are due to war conditions and serious shortage of staff. On the contrary, the Government would not have instituted an inquiry if it had not expected such criticisms. But it explains that the shortcomings are not the result of financial parsimony. The amount expended on health services has increased by well over 50% during the last three years. Every effort will continue to be made to secure more officers, for whom funds have already been provided, and the Council will be asked to vote further funds. But there must be no disappointment if some time elapses before this policy can be fully adopted in the medical department, since hitherto, notwithstanding most urgent representations, it has not been found possible to engage enough experienced administrative officers even for the secretariat.

On the question of the serious shortcomings revealed in the Colonial Hospital, Port-of-Spain, and in the district hospitals, it is stated that the initiative of the Director of Medical Services and of the Government in respect of discipline has been circumscribed by statutory restrictions, and it will be necessary to consider and submit amending legislation to the Council.

Reports of Societies

SULPHONAMIDES AND PENICILLIN IN URINARY DISEASE

A meeting of the Section of Urology of the Royal Society of Medicine was held on April 26, Mr. F. McG. LOUGHNANE presiding, for a discussion on the use of the sulphonamides and penicillin in urinary disease.

Wing-Cmdr. J. C. AINSWORTH-DAVIS said that the introduction of the sulphonamide compounds had proved to be the greatest advance yet made in urinary disinfection. The sulphonamides could be used for both acute and chronic infections, and acted most powerfully on organisms of the coliform, streptococcal (other than *faecalis*), and gonococcal groups. Six basic principles should be observed in their administration: (1) The initial dose, or two doses, to be large, in order to obtain the maximum concentration of the drug in the blood stream in the shortest possible time. (2) Sulphathiazole (which in his experience was the most useful of the compounds) should be administered 4-hourly for at least two days, and unless there were strong reasons to the contrary the patient should be awakened at night for this purpose. (3) A white blood count should be taken before beginning the course, and repeated on alternate days in order to guard against agranulocytosis. (4) Fluid intake during treatment should be increased to at least 5 pints in 24 hours to maintain the urinary output at a minimum of 3 or 4 pints. If the output fell below 2 pints in 24 hours, with pain in the loins and haematuria, blocking was suggested and treatment should cease. (5) Alkalis should be prescribed to be taken by mouth three times a day. (6) It was no longer necessary to withhold sulphur-containing foods such as eggs.

In severe infections endangering life the customary dose should be increased by 50%—that is, 1½ g. instead of 1 g.—and an intravenous injection of from 2 to 4 g. should be given as a preliminary measure. In mild infections or in prophylaxis against urethral fever the dose should be diminished by 50% (0.5 g. instead of 1 g.). For children up to 3 years the dose should be one-third the adult dose; from 4 to 10 years, one-half; and from 11 to 15 years, two-thirds.

Apart from some nausea, headache, and cyanosis there were three main complications which called for cessation of the drug: primary or acquired sensitivity, agranulocytosis, and blocking of renal tubules, pelves, and ureters with crystals. A mild degree of leucopenia need not cause alarm, but a rapid fall in the white blood count to below 4,000 should raise suspicion, and a fall to below 2,500 indicated agranulocytosis.[*] Blocking of renal tubules was due to deposition of crystals of sulphathiazole, which was one of the less soluble sulphonamides, and might occur at any time during treatment and had been known to follow small doses of 5 to 10 g. given by mouth or even one large preliminary injection. The speaker described what he called a ureteric "corkscrew," which, in cases of sulphathiazole anuria, he inserted first in one ureteric orifice and then in the other, giving it a clockwise twist to overcome the obstruction; on withdrawal it would bring with it a mass of crystals.

Penicillin in Urinary Infections

Dr. ROBERT CRUICKSHANK described the properties of penicillin and the organisms against which it was active. Its activity was unimpaired by blood or pus; it had no local or systemic toxicity, but it was unstable in weak solutions and was inactivated by acids or alkalis, by bacterial contaminants, and by heavy metals. He felt that it would be advantageous to keep a considerable degree of laboratory control over the use of penicillin. A medical man finding a case which he thought suitable for its administration should consult with his bacteriological colleague.

The two popular methods of administration were by intramuscular injection intermittently and by intramuscular drip continuously. The drug was rapidly excreted, and therefore if given intermittently it must be at frequent and regular intervals. An earlier view was that the only thing which could be done to delay excretion was to produce nephritis in the patient. Some advance had more recently been made by the use of oily excipients, and one of the amino-acids had also been tried. These methods might help to space out the doses. Intramuscular drip was now commonly used; intravenous drip had been tried but had a tendency to sclerose the veins, and most people, he thought, had given it up. Febrile reactions might be obtained with the use of penicillin, and therefore reliance must be placed upon a temperature chart.

The first and most obvious indication for penicillin therapy in urological infections was staphylococcal infection of the kidney. This was not a very common condition, but it was interesting to remember that after the last war, as a sequel to various injuries giving rise to staphylococcal infections, there was a great increase in perinephric abscess, and this might be repeated. The laboratory methods of diagnosis were: (1) examination of the urine, when the infecting staphylococcus would generally be found, and (2) the white cell count, which, if it got around 20,000 or over, was a strong presumptive sign of staphylococcal infection. In such cases early systemic treatment with penicillin should be recommended, treatment continuing until all clinical signs had disappeared and the urine had been clear for a definite period. Dr. Cruickshank showed the following table to indicate the comparative sensitivity of bacteria to penicillin in urine at *p*H 7.6:

Organism	Inhibitory Level of Penicillin Ratio
Staph. aureus	1/30 unit
Str. faecalis	3 units
B. proteus	8 „
B. coli	30–60 „

Limitations of Penicillin

Mr. CLIFFORD MORSON said that he had had the opportunit of treating a case, in collaboration with Dr. Cruickshank of a severe *Staph. aureus* infection in which it wa suggested that penicillin might be tried. The patient's symptoms were constant backache and frequency of micturitio (every 30 minutes). The treatment consisted of 15,000 unit of penicillin intramuscularly every four hours for five days An interesting point was that after each injection the patien had a good deal of pain in the calf of the leg; but within 4 hours the result was dramatic: the urine became sterile (i had not been sterile for three years) and all the pain in th back disappeared. As each day passed the patient could hol his urine for a longer time, and on the fifth day he was holdin it for two hours day and night. About the tenth day after th beginning of the treatment, however, and five days after i cessation he developed a severe *B. coli* infection, the urin being loaded with this organism; but no other organisms we present, and frequency was as great as before. Penicillin seeme to stimulate the growth of *B. coli*. Incidentally he could n agree with a statement in the Medical Research Council's repo that *B. coli* was sensitive to the sulphonamides. The case became symptomless, but still the urine contained *B. coli*.

Mr. H. P. WINSBURY-WHITE agreed with this last observatio A mild infection with *B. coli* could be got rid of by means a sulphonamide, but it came back again. He added a wor concerning the usefulness of the sulphonamides in prophylax in instrument cases generally. All were familiar with case which required regular and frequent use of instruments, an no matter what care was exercised the patients were subject mild attacks of fever. He had found a small dose of sulpho amide—2 g. a day for three or four days—to control that tendency.

---

[*] A later speaker suggested that the term "granulocytopenia" would be etymologically more correct, "agranulocytosis," strictly speaking, meaning total absence of white cells.

Wing-Cmdr. A. W. Badenoch said that at his R.A.F. hospital they had had a good deal of experience of penicillin, though not much in urological conditions; the field for penicillin in urology was very limited indeed. A few cases of *Staph. aureus* infection uncomplicated by an obstructive factor had responded remarkably well, clearing up in a day or two. They were kept on penicillin for a few days after the urine had become sterile and followed up at the end of the month. Out of rather more than 200 cases in which intramuscular drip had been used, 17 had developed abscesses at the site of the puncture. For this reason they had returned to intermittent injections, the number of which had been cut down and the dosage scaled up. By giving two doses a day of 50,000 units they had been able to get the same clinical results as with 3-hourly doses of 15,000 units.

Choice of Compounds

Mr. E. W. Riches said that his objection to sulphathiazole was that it made the patient feel so extremely ill. He did not think it the best of the sulphonamides to use in urinary infections if consideration were given not only to its potency but to the way in which it was tolerated. He preferred sulphadiazine, given in the same doses; and although some patients were intolerant to sulphadiazine and vomited after it the number was much smaller than with any of the other sulphonamides. He agreed with what had been said about the return of *B. coli* infections, but he thought that in such cases, if a diligent search were made, some cause such as stasis, atony, or trauma in the urinary tract would be found. He preferred mandelic acid for a pure *B. coli* infection, and thought it more effective than any of the sulphonamides. He had seen penicillin used in a number of urinary cases, but in a spinal unit, where there were many complications. The greatest value of penicillin in these cases had been as an "umbrella" under which to operate. The post-operative course had been rather smoother when penicillin had been given immediately preceding the operation. He was sure that it was necessary to go on with penicillin longer than the temperature chart might indicate.

In further discussion Dr. R. A. O'Brien asked whether the leucocyte count was any guide to the safe period when to drop penicillin; also how far one could relieve the patient of the discomfort of frequent intramuscular injections. Dr. A. Stanley suggesed that sulphamezathine was the safest of the compounds and was as effective as the others in urinary cases. Lady Florey said that the pain of intramuscular injection would be reduced when penicillin became more pure as a result of improvements in the manufacturing process. Meanwhile, a good technique on the part of the nursing staff would do much to abate the discomfort.

Wing-Cmdr. Ainsworth-Davis, replying to the discussion, said that he fully agreed as to the value of a short course of sulphonamides before using instruments or before operation, followed by a post-instrumental or post-operative course; the results were very much better. Dr. Cruickshank said that information received from Canada seemed to show that even with inert penicillin, as pure as it could be made, there was a good deal of pain, and there procaine was given as a routine measure. Intermittent muscular injection, with two of the night injections omitted, was, in his experience, preferred by patients to the continuous drip.

DIPHTHERIA ANTIGENS

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine on April 27, with Sir Weldon Dalrymple-Champneys in the chair, an address was given by Sir Percival Hartley, of the National Institute for Medical Research, Hampstead, on diphtheria antigens, their preparation, properties, laboratory testing, and statutory control.

Historical Retrospect

In a short historical survey Sir Percival Hartley said that it was almost 25 years ago in that same Section that Sir Charles Martin communicated observations he had made in Rouen during the last war on the rate of disappearance of diphtheria bacilli from the throat in soldiers. Since then the outstanding event had been the clear demonstration that a considerable degree of protection to individuals and communities could be afforded by active immunization. Until 1913 there had been no simple way of finding out which members of the community needed protection and whether the measures which might be taken would be of any use for that purpose. In that year Schick described his famous test, which changed the whole situation, and Park, a great pioneer in this field, who had not liked the idea of injecting into children a material which caused paralysis in guinea-pigs, became one of the warmest defenders of the Schick test. At a ceremony in New York shortly before his death Park immunized the millionth child, and Schick the first of the second million.

Of all the prophylactics which had been used toxin-antitoxin caused the greatest anxiety to those who made it because the amount of toxin and antitoxin had to be so precisely adjusted. Accidents followed its use, and to those associated with the work the remarkable thing was not that they occurred but that they were so few. For many years until the preparation became obsolete every batch of toxin-antitoxin was tested in his own laboratory at Hampstead before its release was permitted. Some had always maintained that toxoid and not toxin should be the base of all antigens. In 1923 the successful immunization with a toxoid-antitoxin mixture was reported. This preparation had been largely superseded in recent years, but it played a useful part in those early days. It was employed almost entirely in this country. Then came the use of formalin in depriving diphtheria toxin of its toxicity, and for its ease in preparation and its safety the formol toxoid enjoyed wide popularity, while in some European countries and in Canada it was the antigen of choice. Its drawback was its liability to cause unpleasant local reactions, especially in adults. Toxoid-antitoxin floccules for active immunization became popular because the local reaction was only slight; the antigen was particularly suitable for the immunization of adults, and gave as a rule high Schick-conversion rates. In his own laboratory it was shown that while these floccule preparations made a very poor showing on guinea-pig tests for their antigenic activity, they made a good performance when administered to the human; it had then occurred to him that the tests which it was necessary to apply by law to diphtheria prophylactics did not permit this particular kind of antigen to display its qualities.

Alum-precipitated Toxoid

In 1926 Glenny and his colleagues showed that the addition of alum to formol toxoid gave an insoluble precipitate which had high antigenic properties. The antigenic activity of the toxoid was increased from 50 to 100 times by turning it into the insoluble A.P.T., which had advantages not possessed by other forms of prophylactics, and in its modern form was a relatively pure antigen. It was not particularly prone to cause local reactions in young persons, and for the primary immunization of the very young it was the antigen of choice. Its greatest merit was that it was effective in two doses, whereas other forms of prophylactic required three. During this war millions of children had received two injections, and, although it had not been possible to Schick-test them all, in control tests two spaced injections of A.P.T. had given a very high conversion rate. Opinions differed as to whether and when the Schick test should be applied in the immunization campaign, but if the pre- and post-Schick tests were to be omitted, it was with this antigen that this could be done with the greatest justification.

The progress towards active immunization against diphtheria (Sir Percival Hartley continued) had had a series of setbacks owing to fatal accidents following injection of antigen. In Texas in 1919 a number of children died after receiving what should have been a perfectly safe toxin-antitoxin but which contained toxin in amounts lethal to the human subject. These tragic instances created a profound impression and put back the clock, but they brought support to the claim then being worked out in this country for statutory control of certain therapeutic substances. The need had been shown most strikingly in the case of salvarsan; then the discovery of insulin, the demonstration of extreme variability in potency of pituitary extracts, and the whole trend of medical research all pointed in the same direction. It was evident that the manufacture, testing, and supply of specific remedies should not be left to the uncontrolled activities of inexperienced and ignorant persons. Under the Therapeutic Substances Act, 1925, accordingly, diphtheria prophylactics, among other things, might be prepared only by accredited licensees, and licences were granted only to those who could reach and maintain the very high standard demanded in the matter of expert staff and laboratories. All such preparations must conform to standards laid down in respect of purity, potency, and quality.

The Search for a Standard

Sir Percival Hartley confined himself to one aspect of this control—namely, potency. A number of difficulties would be resolved, he said, if potency could be assayed by comparative tests in relation to a standard, and the question had often been asked why, if difficulties of this kind had been overcome in the case of insulin and tuberculin, the arsphenamines, and the vitamins, the same could not be done in the case of diphtheria prophylactic. But the technical difficulties in the assay of antigens were very great. In England not one but several standards would be required, and the methods of comparative testing were very far from being precise.

In the spring of 1941 it was discovered that a brand of A.P.T. of low antigenic activity was being used in the national campaign, and laboratory tests at Hampstead confirmed the low Schick-conversion rates which were reported in the field. Though this A.P.T. was found later to be defective in other ways, these batches did comply with the requirements of the Therapeutic Substances Act, and so far as the potency tests were concerned it was clear that the Schedule itself was defective in ways that had not been anticipated. Primarily this defect was due to the attempt made in 1925 to bring all types of diphtheria prophylactic under the same regulations. In those early days of the Act, when the various prophylactics were reasonably similar in type and of the same order of activity, when antigens made in other countries had to be taken into consideration and brought within the scope of the Act, and when it was quite uncertain how many antigens would have to be legislated for altogether, this policy might have been justified. But with the advent of A.P.T. 50 to 100 times more active than those earlier antigens, these batches of very low potency, good enough to render guinea-pigs Schick-negative, but far below what was required for the immunization of man, could be passed into use.

This was a very serious matter, but it was faced; and action was taken by the Ministry of Health, by medical officers of health, by the licensing authority under the Therapeutic Substances Act, and by the manufacturers themselves and their expert advisers, and the worst consequences of this catastrophe were avoided. He described in detail the laboratory investigations which were carried out. As a result two rigorous requirements were laid down to which all A.P.T. must conform—namely, that the preparation should contain not less than the equivalent of 50 flocculation units of toxoid per c.cm., and that it should be shown that 10 guinea-pigs given two doses of one flocculation unit at an interval of a month must give an antitoxin production of not less than 2 units per c.cm., calculated on the geometric mean.

The results of a number of field and laboratory experiments on manufacturers' samples were shown. The laboratory adopted a standard which was an arbitrarily selected A.P.T., known to give a good showing in guinea-pigs, and subsequently in the field. The manufacturers' samples in this experiment satisfied the two requirements laid down. Arrangements were made for testing the standard in one or more schools alongside the manufacturers' sample, using so far as possible an equal number of children in the groups immunized, and then they were Schick-tested. The standard was found to do all that was expected of it, and by the tests at Hampstead all the samples fulfilled the requirements. This work had not yet been brought to an end, but those concerned felt themselves now on firmer ground than they had been for some time. With regard to the practical business of providing diphtheria prophylactic for the immunization of children, he did not think that any country in the world was better served than our own.

The remarks of speakers in the discussion which followed the address—Dr. R. A. O'Brien, Mr. A. T. Glenny, Dr. H. J. Parish, and others—were all in the vein of reminiscence.

Correspondence

An Undergraduate Medical School at Oxford

SIR,—The report of the Goodenough Committee has been received with little open criticism, partly because any medical school which refuses to fall in with its recommendations is likely to find itself at a considerable financial disadvantage. As Oxford graduates, however, we feel bound to put forward some criticisms of that section of the report which deals with the University of Oxford (Chapter 6, paras. 41-52, pp. 122 to 125).

Shorn of its trimmings the suggestion put forward by the university and apparently approved by the Goodenough report amounts to the foundation of an undergraduate clinical school to train "teachers, investigators, and consultants rather than general practitioners." This involves two assumptions which we believe to be quite unjustified: the first, that medical students before having started on the clinical period are in a position to determine what type of medical career they wish to take up; the second, that there is at this stage in their education any means of selecting those who are likely to prove efficient "teachers, investigators and consultants."

We teachers who have long been in close touch with undergraduate medical schools realize only too well that it is impossible to prognosticate the development of any particular medical student during his three years of clinical work. Some who have covered themselves with honours in the pre-clinical period fail lamentably as clinicians; others with chequered careers in their pre-clinical studies may ultimately prove quite outstanding both as clinicians and as teachers.

It must be remembered that some of the greatest figures in medicine—for example, Sir James Mackenzie—spent many years as general practitioners. It may well be that every potential consultant or teacher would benefit far more by a period in general practice than by three years of study in the "rarefied atmosphere" (*vide* Goodenough report, p. 124) of Oxford. Few undergraduates go down from Oxford without feelings of poignant regret, and many medical students at the impressionable age at which they normally leave Oxford would wish to remain there to complete their clinical studies. As a result the suggested undergraduate school would be likely to be filled mainly by those with sentimental attachments to Oxford. Those who, perhaps, with the assistance of their parents, took a broader view of their future medical education would continue to go to teaching hospitals in London or elsewhere.

It is probable that should such an undergraduate school as is envisaged in the Goodenough report come into being it would within a few years die of inanition. In the meantime, however, it might well have dealt a severe blow to the opportunities for research and postgraduate teaching which were visualized as the fruit of Viscount Nuffield's benefactions. The Nuffield professors were not selected with a view to their becoming teachers of undergraduates, and the strain of an undergraduate teaching school would necessarily considerably restrict their more vital functions. We trust that the university will not attempt to implement the recommendations in the report without further consideration.—We are, etc.,

Chronic Otorrhoea

SIR,—Mr. Thacker Neville (April 28, p. 594) draws attention once more to the extremely satisfactory results obtained by the dry treatment of chronic otorrhoea. In 1931 I[1] recorded that over 80% of cases of chronic otorrhoea in school-children responded promptly to the daily aural insufflation of a powder consisting of 1% iodine in boric acid. In some cases cauterization of the sessile granulations by 50% silver nitrate solution was undertaken. I also recorded[2] the view that before any case of chronic otorrhoea is referred for operation at least 12 weeks' continuous treatment with the powder should be completed. The powder is made by thoroughly mixing the iodine crystals with the boric acid powder in a mortar and storing in a glass-stoppered bottle. Since 1931 the aurists to the L.C.C. (who annually treat some 4,000 cases of chronic otorrhoea in school-children) have used this powder with similar satisfactory results. Mr. Scott Stevenson has expressed the opinion that I had underestimated the good results of the treatment of chronic otorrhoea with this powder. The insufflation iodidi cum acidi borici is the formula used by the L.C.C. Since 1931 the powder treatment of chronic otorrhoea has spread and is generally accepted.

Until all writers on chronic otorrhoea classify their cases it is impossible to draw any deduction from statistics of their results. Dr. A. G. Wells,[3] chief aurist to the L.C.C., has drawn up the following classification, which I consider an excellent one:

1. Tympanic or tubo-tympanic infection (66% of all cases in school-children fall into this group). This is associated with a central perforation, small or large, temporary or permanent. It is this type of case which, with due attention to the causal nasopharyngeal infection, responds 100% to the dry treatment; in many cases the use of plain boric acid powder suffices. This type of case rarely becomes complicated and rarely requires operation on the mastoid.
2. Tympanic infection with granulations (9% of all cases in children). Where the granulations are sessile, repeated cauterization with 50% silver nitrate solution and the use of iodine-boric powder will cure over 50% of cases. Where the granulations are exuberant, conservative treatment is useless and operation is indicated.
3. Attic disease (4% of cases in children). Should there be no response to powder treatment in 12 weeks operation is indicated.
4. Aural polypi } About 6% of all cases.
5. Cholesteatoma }

Both these types require operation forthwith. 50% of all intracranial complications of otorrhoea are associated with these lesions. If such cases are treated promptly by operation these complications do not occur.

The L.C.C. as a result of its thorough treatment of chronic otorrhoea in school-children over a period of years has literally wiped out the incidence of lateral sinus thrombosis, brain abscess, and meningitis arising from chronic otorrhoea. A personal experience of fifteen years as aurist to the L.C.C. and twenty years' hospital practice has revealed that all cases of intracranial complications associated with chronic otorrhoea have developed in patients in whom treatment has been neglected and no operation undertaken.

On the other hand chronic otorrhoea is also a preventable disease and is almost unknown in the well-to-do population. Wilfred Trotter stated that the tuberculous joint was a disease of the poor, and the same may be said of chronic otorrhoea. Prompt and active treatment of all cases of *acute* otorrhoea will prevent the development of *chronic* otorrhoea, and in attaining this end the use of conservative mastoid surgery should be exploited to the full, at an early stage of the causal acute infection.—I am, etc.,

London, W.1. N. ASHERSON.

Newer Concepts of Breast-feeding

SIR,—I entirely agree with the first half of the letter by Mr. Eric Coldrey (April 14, p. 530) on this subject, and I would like to add other causes and remedies which I have found in advising a large number of mothers during this war and in successfully breast-feeding two babies myself.

(*a*) Worry and lack of rest. These have unfortunately been big factors: anxiety about husbands; all the worry of seeing about the baby's rations, extra milk, cod-liver oil and orange-juice, etc., which have to be dealt with very soon after arriving home; so much of this seems unavoidable, but advice from the doctor to have one hour's sleep in the afternoon and sit with the legs up while sewing in the evening can have a marked effect.

(*b*) Very full painful breasts when the milk first comes in, and 7 to 14 days later insufficient milk. If fluids are restricted on the third day after delivery when milk is first coming in and subsequently increased according to the merits of each case, the breasts scarcely become painful at all; the baby is not choked by getting the milk too quickly, and there is not the risk of pressure atrophy on the milk glands from too full breasts. Some mothers can take fluid in large quantities again on the 4th and 5th days, but in others, and especially multiparae, restriction may be necessary up to the 10th to 14th day. (I found this necessary with my second baby.)

(*c*) Decrease in quantity of milk when the mother first gets up and at one month when she is trying to undertake more household duties. The feeds which are commonly affected are the 2 p.m. and 10 p.m. ones, and from experience I have found (despite Dr. Coldrey's remarks to the contrary) that a 2-oz. complementary feed following one or both of these feeds will very often tide the mother over these periods provided everything possible is done to encourage the mother's milk and she is told that this is a temporary measure only and will be unnecessary in one to two weeks' time. The great advantage of not having a hungry crying baby in the afternoon and during the night is that the mother gets much more rest and ease of mind, which are such big factors in promoting lactation.

One last point. I don't know whether Dr. Coldrey erroneously used the word "sick" visitor for "health" visitor, but the person he describes closely resembles what are known in this country as "health visitors," and I would like to point out that he has made very sweeping statements on the evidence of one bad specimen of this type of highly qualified nurse. In my experience in this country I have not met one health visitor who did not take the utmost trouble to encourage every mother to breast-feed her baby, and it is, in fact, in the essence of their teaching.—I am, etc.,

Dorking, Surrey. MARY C. JEFFRIES.

Women in Labour

SIR,—Dr. John Elam's letter (April 7, p. 495) draws attention to a matter which should, I feel, give reason for some heart-searching in the profession.

The necessarily dispassionate detachment with which the doctor makes his diagnosis and devises treatment is too often exaggerated into a completely, though not consciously, callous attitude to the distress and "humanity" of his patient. This is to be seen nowhere so regularly and so markedly as it is in the field of midwifery. It seems that those whose professional life is concerned with women in labour, through the presence of severe pain as a constant background to their work, unconsciously come to accept it as inevitable and to lose any sense of reaction against it.

While my ship was in an American port recently I was privileged to attend the course in continuous caudal analgesia at the Pennsylvania Lying-in Hospital, Philadelphia, conducted by the originators of this continuous method, Drs. R. A. Hingson and W. B. Edwards. Their results in the relief of pain in labour are dramatic and complete. The method, as they teach, has definite limitations and does somewhat alter the normal course of labour; it does call for increased time and skill from the obstetrician and anaesthetist. This would seem to be a worth-while price to pay for the relief of one of the severest, and certainly most frequent, pains with which Nature afflicts our race. If men and all women were called upon to bear it I have no doubt that this statement would meet with virtually unanimous agreement.

In May, 1944, Dr. Hingson could state that more than 30,000 births had been managed with this technique in more than half the countries of the world (*Amer. J. Obstet. Gynec.*, **47**, No. 5), and it can surely be pronounced past any merely "experimental" stage. In March, 1945, I can find one British hospital in which the technique has been attempted, and there courageously under considerable difficulties. I can find no other evidence of active interest elsewhere.

In reply to Dr. Elam's very understandable challenge in his closing sentence I would like to assure him that there are very many of us representing "youth," but whose fingers are being kept far from the "helm" by the exigencies of the three Services. We are trying to keep alive in ourselves, in frustrating circumstances and with a wholly nebulous future, that spirit of practical idealism so well exemplified by his letter.—I am, etc.,

T. B. FITZGERALD,
Surg.-Lieut.-Cmdr., R.N.V.R.

SIR,—I write in support of Dr. John Elam's (April 7, p. 495) and Dr. R. J. Minnitt's (April 28, p. 607) comments on gas-air analgesia. Publicity in the newspapers has impressed the midwives and their authorities with the necessity for relieving pain in labour, but their training in such methods as are available is often farcical. I agree with Dr. Minnitt that until there is a standardized curriculum for special instruction and a *central* examination instituted it is impossible for reasonable standards to be maintained, and the present methods of analgesia are merely brought into discredit.—I am, etc.,

London, W.1. K. G. LLOYD-WILLIAMS.

SIR,—The various viewpoints expressed on this subject in recent letters have been most interesting. When all is said and done, however, there are five factors which govern the present lamentable state of analgesia in labour: apathy, conservatism, prejudice, lack of apparatus or facilities, and lack of anaesthetists. Of these, the first three are by far the most important, as they govern—or rather misgovern—*policy*, and without a progressive policy nothing spectacular will ever be done about the last two.

With regard to apathy and conservatism, I well remember watching the face of a certain midwife during a Caesarean section under caudal analgesia. I was not then very conversant with the technique, and analgesia was not as perfect as I would have wished; consequently the patient suffered some mild discomfort during the latter stages of the operation. The attendant midwife wore an expression of considerable alarm, although an hour later she exhibited no concern whatever over the agony of a young and frightened primipara in labour. She was conditioned to perfect anaesthesia in the operating theatre and to imperfect analgesia—or none at all—in the labour ward, and was completely unaware of the inconsistency of her attitude.

Prejudice was once discussed by Lord Lister in the following manner:

> "When I was a little boy I used to imagine that prejudice was a thing peculiar to some individuals. But, alas! I have since learned that we are all under its influence, and that it is only a question of degree. But let us ever contend against it: and remembering that the glorious truth is always present let us strive patiently and humbly to discover it." (Graduation Address—1876.)

Were all of us concerned to search our hearts in the light of these words I feel sure that many more women in labour would have an easier time; and that newer methods of securing analgesia would come in for less ill-informed criticism.—I am, etc.,

Sutton, Surrey. A. H. GALLEY.

SIR,—"Mother and Doctor" (April 28, p. 608) hits the nail on the head when she says that the majority of people in attendance at a labour seem to imagine that the patient is "making a fuss."

Having quite recently "strafed" a midwife who, though she had four children of her own, criticized my giving analgesics in labour, I feel that some midwives take an almost sadistic joy in withholding sedatives from mothers in labour. Although I have made real efforts to have sedatives available in the labour ward for every midwifery case of mine, I find the nurse nearly always has a reason for not giving it. The usual answers are that it means doing an extra P.V. to see how far on the patient is or that "the mother is having good pains and coming on fine without it." As a mere male I cannot understand this callous attitude on the part of one woman to another which seems to develop as soon as a midwife enters an institution or maternity home.

Out on the "District" things are different: the nurse treats the mother as a real charge on her sympathies, and if she knows the doctor is anxious to relieve the pains of labour she very soon lets the doctor know that she is willing to co-operate, and will follow to the letter instructions given for administration of a sedative.

I do not mean to put *all* the blame for the lack of help in the relief of labour pains at the door of the nurse, but when in my own experience I have seen drugs withheld when they were actually freely available I feel the nurse's outlook on pain must be sadly warped. Why the difference in attitude between hospital and district nursing? I cannot imagine the reason.—I am, etc.,

Crewe. J. K. B. WADDINGTON.

SIR,—On what authority or evidence does your correspondent "Mother and Doctor" make the extraordinary allegation that nurses in charge of women in labour have "often neither the knowledge *nor the desire* to mitigate the suffering"? (my italics). Any lack of knowledge is not the fault but rather the misfortune of the nurse. To state that members of the nursing profession do not wish to save their patients all possible suffering is a slander which cannot be allowed to go unchallenged. Such unsupported statements recall Kipling's "Female of the Species": "Unprovoked and awful charges, even so the she-bear fights; speech that rips, corrodes, and poisons, even so the cobra bites."—I am, etc.,

Kirkconnel. BOWMAN EDGAR.

Detection of Nicotinic Acid Deficiency

SIR,—I read with great interest your annotation on this subject (April 21, p. 561). I feel compelled, however, to make a few comments on a number of minor errors, and particularly on the last sentence of your article.

The minor errors are: (*a*) It was not Coulson, Ellinger, and Holden[1] but Sarrett[2] and Huff and Perlzweig[3] who proved that most of the so-called trigonelline found by earlier methods is really nicotinamide methochloride. (*b*) Ellinger and Coulson[4] found that not only nicotinamide methochloride but also the genuine nicotinamide metabolite in urine is non-fluorescent. (*c*) Najjar, White, and Scott[5] did not "isolate F_2 in crystalline form," but obtained crystals from an F_2 concentrate, the analysis of the crystals yielding results not corresponding to the postulated formula. There is no evidence in favour but some against F_2 being a butyl ether of N-methyl nicotinamide-carbinol (Ellinger[6]). (*d*) Najjar[7] in his latest paper "proposed a test . . . based on the measurement of N-methyl nicotinamide chloride in the urine instead of the fluorimetric measurement of F_2." He uses this fluorimetric measurement, but compares the fluorescence intensity of F_2 with that of a fluorescent standard derived from nicotinamide methochloride instead of a quinine sulphate standard; this had already been done earlier by Huff and Perlzweig[8] and Coulson, Ellinger, and Holden.[1] (*e*) The minimum nicotinamide methochloride output in normal people after the intake of 100 mg. nicotinamide is considered by Najjar[7] to be "2.1 g."; 2.1 mg. is, of course, the correct value.

In the conclusion it was stated that "we still have no simple laboratory method for estimating the level of nicotinic acid nutrition in man." This conclusion is based: (*a*) on the observation of Ellinger and Coulson[4] that the extent of the elimination of nicotinamide methochloride depends on a number of factors other than the intake of nicotinic acid, such as exercise, food, the presence of methyl donators in the tissues, and the efficiency of the methylating mechanism of the body; and (*b*) on the failure of Sargent, Robinson, and Johnson[9] and Mickelsen[10] to find an increase in nicotinamide methochloride output after nicotinamide intake. The results of these last two papers disagree with all the findings of other investigators, most of which are not quoted in your annotation. Moreover, the findings of Sargent, Robinson, and Johnson are valueless, as they have been carried out with an obsolete method already abandoned by its author, Najjar. The values given by them for normal people are in the order of one-hundredth of those found with three different reliable methods by numerous other workers, and the estimation of the response to ingested nicotinamide was carried out on 1- or 3-hour samples 12 hours after the intake of nicotinamide, when at least 90% of it was eliminated. Mickelsen[10] and Mickelsen and Erickson[11] did not compare the response to different amounts of nicotinic acid in the same person, but in different persons, and tried too small amounts to give a discernible rise in nicotinamide output (Ellinger and Coulson[4]). Exercise and food intake can be controlled during the testing period. Lack of sufficient available methyl-donators and damage to the methylating mechanism as might be present in certain liver diseases (Ellinger and Benesch[12]) might reduce the specificity of the test to a certain degree; but both these facts can be ascertained.

No direct relation between nicotinamide intake—dietary or extradietary—and nicotinamide methochloride elimination can, however, be expected since an overwhelming proportion of the nicotinamide requirement of the human body is covered, not by the dietary intake but by the release of this substance by the intestinal flora (Ellinger, Coulson, and Benesch[13]; Ellinger, Benesch, and Kay[14]). The nicotinamide methochloride elimination in urine provides, however, a solid basis for the assessment of the level of the nicotinamide state of the human body. Three methods can be used: the estimation of the basic 24-hour output without extradietary intake of nicotinamide, the response to a single dose, or to 4 or 5 doses of nicotinamide on consecutive days. Investigations carried out by various workers using one or more of these methods (Huff and Perlzweig,[3] Ellinger and Coulson,[4] Ellinger, Coulson, and Benesch,[13] Ruffin, Cayer, and Perlzweig,[15] Coulson, Ellinger, and Smart,[16] Ellinger, Benesch, and Kay,[14] Ellinger, Benesch, and Hardwick,[17] and Hochberg, Melnick, and Oser[18]) provide values for the average basic nicotinamide methochloride output and for the responses to ingested nicotinamide in healthy man, which are in good agreement in spite of the great individual fluctuations of the nicotinamide methochloride elimination, and in spite of the fact that the nicotinamide methochloride assay in the urine was carried out by at least three entirely different methods. When cases with clinical symptoms of nicotinamide deficiency were examined[14 15 17] much (50 to 80%) lower values for both average basic output and response to ingested nicotinamide were observed.

This agreement and the great differences between healthy and deficient people prove the reliability of the method if all recommended precautions are taken.—I am, etc.,

P. ELLINGER.

Infection from Dead Teeth

SIR,—I read the article on pulpless teeth by Prof. E. Sprawson and others (April 21, p. 551). I will not quarrel with what is written, but I would like to point out a few omissions.

1. The loss of the nerve supply of a tooth should render the tooth subject to trophic changes and more liable to infection and less able to fight back. This is true in syringomyelia and tabes. Why is it always neglected by writers on dead teeth?

2. The sterilization of root canal does not guarantee sterility of dentinal tubules. The authors by implication say that "if you can be sure of a sterile root canal carry on the vicious practice of filling dead teeth." And yet it is admitted that it s next to impossible to check the harm to general health done by these foci of infection. The *x* rays are useless, and duodenal or gastric ulcer or rheumatism or anaemias can always be seen by doctors. Dentists do the damage, and doctors have to do he salvaging. Incidentally doctors are now arguing openly hus: extraction of bad teeth does not cure, so why extract? orgetting that to cure a cut throat you have to do more than emove a razor!

I would like to ask the authors the following questions: (*a*) How many pulpless teeth have they examined after five years rom the date of filling the roots and how many were found terile? (*b*) What number of people with dead teeth have been examined completely—i.e., by test meals, *x* rays, blood counts, etc.—after ten years, and what is the standard of health in them as compared with similar class without dead teeth? Obviously a "follow-through" is most essential for the dental profession if it wishes to remain part of the healing profession; otherwise it is likely to become no more than a manicuring or plumbing "profession."

So far as I can make out the average dentist's standard is, "The patient is satisfied." With this as his motto no one can accuse him of aiming too high. In my view it would be a service to humanity if leaders like Prof. Sprawson condemned without qualification all root fillings.—I am, etc.,

Hearing Aids

SIR,—The letter of Mr. O. C. Leadbitter (April 28, p. 210), president of the Hearing Aid Manufacturers Association, raises an issue of national importance. A good hearing aid to-day costs about £20 to £30, and it appears that we may not look forward to any considerable reduction. This will be a severe blow to the deafened and to those doctors and social workers who have devoted themselves to this problem.

Mr. Leadbitter speaks with undoubted authority, and I am happy to pay tribute to him and his fellow manufacturers. The development of the modern hearing aid is largely due to the enterprise of his association, and the deafened have much to be grateful for. It must be remembered, none the less, that business firms, however well-meaning, cannot run at a loss, and in view of the present impasse it behoves us to consider in what way their function may be supplemented. The cost of a hearing aid may be allocated as follows: (*a*) Components—primary cost of, (*b*) distribution, (*c*) research, (*d*) Government taxes, (*e*) profits.

(*a*) *The Components* in a three-valve hearing aid may be listed as follows: (i) container, (ii) batteries, (iii) telephone, (iv) microphone, (v) valves, (vi) transformer, (vii) potentiometer volume control, (viii) chokes and condensers for intervalve couplings. The circuit is simple and standard. Most of these components are manufactured by primary producing companies. It is, in fact, possible for a "hearing-aid" manufacturer to purvey an instrument without having himself produced a single component.

(*b*) *Distribution.*—This must be subdivided again into (i) advertisement, (ii) sales, (iii) maintenance. It is not easy to comment without prejudice on these features, but it is certainly to be deprecated that the cost of an instrument should in any way be enhanced by the sterile element of private advertising. A similar criticism applies to sales. Shop rentals, salaries, and commissions must all be paid for, and the private manufacturer has perforce to establish his centres at strategic points. In a few large towns unnecessary overlapping occurs, whilst large areas are left badly provided for. Maintenance is a heavy burden. Many patients have already written to you feelingly on this point.

(*c*) *Research.*—Much remains to be done in this direction, and the medical profession is admittedly partly to blame. The technical problems are clearly recognized. Components must be reduced to minimum size compatible with efficiency and consistency. Modern service equipment already incorporates many such improved units which should be made available without further delay. Adequate co-ordination between clinician and physicist is unfortunately still lacking. Much remains to be done in the correlation of patient and instrument.

(*d*) *Government Taxes.*—It would be interesting to know how much these amount to, and it is difficult to believe that enlightened public opinion will tolerate their continued imposition. It should surely not be impossible to abolish purchase and similar taxes in such a deserving cause.

(*e*) *Profits.*—The above analysis contains many implied criticisms of a destructive nature, and it may well be asked what constructive proposals are available. It behoves us to await the authoritative findings of the four committees to which Mr. Leadbitter has already referred, but as these are not yet available the following expression of a purely individual opinion is perhaps permissible.

(1) I believe that the hearing-aid manufacturer would welcome the opportunity of producing a first-class instrument at a reasonable price if he could be relieved of the responsibility of distributing it.

(2) Advertisement—in so far as it is at all necessary—should be in the hands of the National Institute for the Deaf and related bodies.

(3) Distribution should be undertaken by regional hearing-aid centres. These are urgently needed and should be opened in every large town. The late Dr. Tookey Kerridge did much pioneer work in this direction, and the achievements of Drs. Ewing and Littler in Manchester cannot be too highly praised. Individual efforts, however, cannot cope with this nation-wide problem. Many more

clinics must be established. Every deafened individual should be able to make contact with such a clinic. Provision should be made not only for testing but also for supplying and maintaining the most suitable instrument.

Standardization is essential, and this brings us to the question of research. I do not wish to digress into technical details, but I am firmly of the opinion that no more than two, or at most three, different models of valve instrument are justifiable. Competitive private production unfortunately results in multiplicity of instruments which merely differ in inessentials, such as plugs, shape of box, and so on. Further research is essential, and in this the otologist must collaborate with the physicist. It is imperative to produce adequate testing instruments. The pure-tone audiometer is valuable but inadequate. We urgently need standardized intelligibility tests. The physicist must design and produce his models with accurate specification of performance, and the otologist must support him in assessing the value of each model in different types of deafness. In this way it should be possible to produce standardized instruments at less than half the present cost. Blue-prints could be circularized widely so that simple replacements and running repairs could be done by any radio shop, while the original sale would be made on the basis of adequate intelligibility tests in the regional centre.

Such a scheme is undoubtedly a counsel of perfection. The difficulties are many and obvious, but it is clear that the good will of all parties is not lacking, and under the authoritative guidance of the present official bodies we may look forward to an adequate solution of this grave problem.—I am, etc.,

Liverpool. A Tumarkin.

Prolonged Use of Minimal Doses of Sulphonamides

Sir,—It is rightly recommended in acute infections that where sulphonamide chemotherapy is used it should be administered in full doses, and that the blood concentration should be kept at an efficient bacteriostatic level for the duration of the course, which is limited usually to 7 or 8 days. The question of the use of sulphonamide drugs in chronic or subacute conditions has received little attention in the published literature, and the following observations may not be without interest.

Helmholz in the *Proceedings of the Special Meeting of the Mayo Clinic* (1941, **16**, 145) reported the use of small doses of sulphathiazole in the treatment of a case of chronic urinary tract infection. He found that quite low concentrations (4 to 5 mg. per 100 c.cm.) of sulphathiazole in the urine were sufficient to keep the infection under control, and this was given without any ill effect for a period of 7 weeks up to the time of writing. This concentration was obtained by administering less than 0.4 g. of sulphathiazole by mouth per day. There are records of other cases where an even smaller dosage has been effective and has been given without untoward reaction for very much longer periods of time. Although brief mention is made of it in the M.R.C. pamphlet No. 10, entitled "The Medical Use of Sulphonamides," on page 21, it is evident that this method of dealing with chronic and subacute urinary infection is not well known, and one feels that it is worthy of emphasis.

Among other conditions of urinary infection where the method might be employed with effect are certain cases of pyelitis of pregnancy; as a rule early dosage of sulphathiazole (about 4 g.) per day for four days will clear up the condition, but in a certain number of cases this is followed by relapse and the course has to be repeated sometimes as many as three or four times. It is suggested that in cases where a relapse has occurred the treatment should be recommended with a dose of about 2 g. sulphathiazole per day for two to three days, and this gradually reduced to as small a dose as will keep the infection under control and the urine free from pus. This dosage, which may be as low as 1/2 g. every day, may be continued for 4 to 8 weeks until about the 30th week of pregnancy, when the condition tends to resolve naturally. In the case quoted sulphathiazole was used, although it would appear that sulphadiazine would be equally, if not more, effective in view of its slower rate of excretion.

It will thus be seen that the quantity of drug administered is certainly not more than 3½ g. per week, and therefore the amount given in four weeks is less than that given in the normal course (16 g. in 4 days). The adoption of this technique has, one feels, much to support it and would appear to offer a useful means of overcoming the associated toxaemia, anaemia, discomfort, and, in many cases, the inconvenience of a stay in hospital.
